A total of 411 patients with a diagnosis of TIA between January 1st, 2004 and December 31st, 2008, were included in CARE registry. However, 203 patients did not fulfil the inclusion criteria for the present study: 76 did not have a CRP level measurement within 48 hours of TIA onset; 65 patients had a previous stroke; 27 patients had a history of recent infection; 15 patients had a history of cancer, 10 patients had a history of chronic inflammatory disease; and in 10 patients, data on the TIA duration were missing.

Figure 1. Receiver operating characteristic curves for the ABCD score and CRP level

Figure 2 A. Area under the receiver operating characteristic curve (AUC) for two different predictive models.

Figure 2 B. Mean Predicted Probability among TIA patients who experienced an incident ischaemic stroke and those who did not, based on ABCD2-only Model and ABCD2+CRP Model.

Figure 2 C. Graphical comparison between ABCD2-only Model and ABCD2+CRP Model, based on a ‘net’ benefit.

Therefore, the analysis for the present study was performed for the remaining 208 patients. Patients were evaluated at the EW (85%) and at the SC (15%). The median time between the onset of symptoms was 2.55 hours (95% CI 2 to 3.1). All patients underwent brain CT scan at a median time of 4.0 hours (95% CI 3.5 to 4.5) after symptoms onset. Of the 208 patients, 76 underwent a cerebral MRI during the acute phase, 38 patients in the CRP < 3 mg/L group (diffusion-weighted imaging (DWI) was positive in 4 patients) and 38 patients in the CRP ≥ 3 ml/L group (DWI was positive in 5 patients).

The difference between the number of DWI positive patients in the two subgroups was not statistically significant ($p = 0.68$). The median CRP levels was 3 mg/L (interquartile range

2 to 7). None of these patients had a recurrence before CRP measurement. The analysis of the ROC curves revealed that a CRP level of 3 mg/L was the best cut-off point for predicting the occurrence of end-point events and optimising of the sensitivity-specificity ratio (sensitivity = 0.70; specificity = 0.54; AUC = 0.65; 95% CI, 0.58 to 0.71; $p = 0.0004$); and ABCD score = 4 (sensitivity = 0.50; specificity = 0.69; AUC = 0.67; 95% CI, 0.60 to 0.73; $p < 0.0001$) (Figure 1). Accordingly, patients were divided into two subgroups: CRP level < 3 mg/L or CRP level ≥ 3 mg/L.

Demographic data, cardiovascular risk factors, baseline laboratory parameters, characteristics of the TIA patients, and therapy at discharge according to the CRP cut-off are reported in Table 1. The CRP ≥ 3 mg/L group was significantly older than the other group ($p < 0.018$), and the patients were more frequently diabetic. For secondary prevention at discharge, of the 208 patients, 170 (82%) were treated with antithrombotic medication; 31 patients (15%) were treated with warfarin (according to the international normalised ratio range between 2.5 and 3.5); and 7 patients (3%) did not receive any secondary prevention treatment. At discharge, a blood pressure-lowering medication was administered to 152 (73%) patients, lipid-lowering treatment (dose range between 10 and 40 mg/die) was administered to 34 (16%) patients and anti-diabetic medication was administered to 27 (13%) patients. No statistically significant difference for ischaemic stroke was found at the 28-days and 1-year follow-up based on the comparison of all of the patients ($n = 411$) included in CARE registry vs. the subgroup study analysis ($n = 208$): 8% vs. 11% ($p = 0.2$) and 15% vs. 18% ($p = 0.3$), respectively. During the 3.7 years of follow-up, 48 patients experienced an ischaemic stroke. The hazard ratios for ABCD² ≥ 4 and CRP ≥ 3 based on the Cox regression model was statistically significant for CRP (HR = 2.95, $p = 0.005$) (Table 2). The ROC curves for the ABCD²-only Model and ABCD²+CRP Model are presented in Figure 2A. AIC (Akaike Information Criterion) decreased from 486 to 479 on addition of CRP.

Table 2. Cox regression coefficients based on ABCD²-only Model and ABCD²+CRP Model of stroke events

Prognostic variables	Parameter estimate	Standard error	p values	Hazard Ratio	95% CI
Model ABCD ² -only (significance level =0.0004)					
ABCD ² score ≥ 4	1,32	0,44	0,0024	3,76	1,60 - 8,81
Model ABCD ² +CRP (significance level <0.0001)					
ABCD ² score ≥ 4	1,13	0,44	0,0101	3,10	1,32 - 7,33
CRP ≥ 3 mg/l	1,08	0,39	0,0056	2,96	1,38 - 6,34

The corresponding AUCs were 0.622 and 0.691, based on ABCD²-only Model and ABCD²+CRP Model, respectively, with a statistically significant difference ($p=0.028$), that showed an increase of 11.1%. The odds ratios were 3.34 (CI 95% 1.31 to 8.50, $p = 0.01$) and 3.35 (CI 95% 1.45 to 7.74, $p = 0.004$). for ABCD²-only Model and for ABCD²+CRP Model, respectively. Figure 2B illustrates the mean predicted probability of an ischaemic stroke based on ABCD²-only Model and ABCD²+CRP Model in those subjects who experienced an

ischaemic stroke and in those who did not have. The absolute Integrated Discrimination Improvement (IDI) was 0.0438 ($p < 0.001$), and the relative IDI was 0.8926. The net benefit became significant from a predicted probability $\geq 20\%$; 42 patients were true positive (TP), 101 were false positives (FP) and the NET was 0.080 based on ABCD²-only Model, 36 patients were TP, 63 were FP and the NET was 0.097 based on ABCD²+CRP Model (Figure 2C).

Table 3. Cox regression coefficients for CRP and ABCD² score for cerebro- and cardiovascular events and vascular mortality

Prognostic variables	Parameter estimate	Standard error	p values	Hazard Ratio	95% CI
ABCD2 score ≥ 4	1,35	0,40	0,0008	3,85	1,75 - 8,46
CRP ≥ 3 mg/l	0,98	0,32	0,0025	2,65	1,42 - 4,97

DISCUSSION

The usefulness of a biomarker in clinical medicine depends on whether it gives informations to the clinicians by reliably identifying groups with a specific prognosis. This study produced useful findings for TIA prediction. Using a population-based registry, we prospectively assessed the ability of CRP levels, compared to known risk factors expressed as the ABCD² score, to predict ischaemic events. Routine CRP measurements might be a useful tool for identifying TIA patients who are at a higher risk of ischaemic stroke. Our findings support the concept of a CRP-level cut-off of 3 mg/L may as an helpful predictor of cerebral ischaemic events in TIA patients. However, it is necessary to exclude all patients with concurrent infection or inflammatory disease, which may alter CRP levels and confound the results. Several biomarkers have been evaluated for risk prediction in ischaemic conditions, and CRP was shown to be a powerful predictor of future coronary and cerebral ischaemic events [1-3].

Previous studies demonstrated a strong predictive association between elevated CRP concentrations and future atherothrombotic events (stroke, coronary events and peripheral arterial disease) [24]. High CRP levels represent a strong risk predictor for subsequent ischaemic stroke among patients with preexisting atherothrombotic disease [25]. High CRP levels are associated with intima media thickness, development of atherosclerotic plaques, their progression, rupture and ischaemic stroke [26]. Many possible mechanisms of a direct action of CRP on vascular cells have been reported. CRP plays an important role in the immune response and is implicated in the development and complications of atherosclerosis [2, 6]. High CRP levels may up-regulate adhesion molecules and chemokine expression, which promote vascular inflammation [27]. A meta-analysis of studies with long-term follow-up (> 8 years) showed that the risk for stroke in healthy individuals in the highest quartile of CRP concentrations increased nearly 70% compared with those in the lowest quartile [28].

There has been much interest in identifying prognostic indicators that can be used to determine which patients are at a higher risk of stroke after TIA. The risk of stroke after TIA has been reported to be 2% to 4% at 2 days, approximately 6% at 7 days, and of 10% to 15% at 90 days [13, 31]. Recently, an effort has been made to risk stratify patients who present with TIA using clinical scoring (ABCD system) [14]. This score has the advantage of using easily assessable clinical variables. However, some patients have strokes despite a low predicted risk according to this score. In a systemic review of stroke risk after TIA using the ABCD system, it was estimated that the early risk of stroke varies according to the clinical speciality of the examining physician, the evaluation setting, the method of data extraction and the limited number of outcome events [31]. The ABCD² system is considered to be the best available method for determining which patients are at short-term risk for stroke after TIA although the clinical judgment and the data from multiple sources, such as imaging and biochemistry, must be incorporated into the score. In addition, a recent study showed that the inclusion of brain and carotid imaging into the ABCD² score improved the risk stratification after TIA in secondary care settings [31]. However, the prognostic value of the ABCD-score or the ABCD²-score has been questioned recently [13, 31]. There have been only few studies that evaluated biomarkers exclusively in patients with TIA, however their methodology and evaluated outcomes were different [10, 11]. There was no relationship between CRP and outcome in a single study where the ABCD score and biomarkers for risk-stratification were compared [11]. High-sensitivity CRP serum level predicts further ischaemic events following TIA [10].

The baseline characteristics of the current study (age, gender, and clinical features) were comparable to most of the aforementioned studies [10-14,31]. However our study was not designed to investigate the rationale for decision making in the care of TIA patients. Higher CRP levels in our data are related to a larger number of vascular events and vascular deaths when compared to the ABCD² ≥ 4 score alone. It has to be noted that the higher CRP group was significantly older than the lower CRP group. Moreover, the high rate risk of stroke in our cohort might be due to limited statin use. Statins have pleiotropic effects, including anti-inflammatory actions. Statins reduce plasma CRP levels and this decrease is independent of LDL cholesterol reduction [29]. Although a weak association between cholesterol and stroke has been shown in the past, a decrease in cholesterol concentrations with statins can reduce the incidence of stroke in high-risk populations [9, 33] and in patients with a history of TIA or stroke [30]. There are no large randomised, controlled trials that indicate that lowering of CRP levels should be a secondary prevention strategy in TIA or stroke patients. A recent trial on apparently healthy individuals with high levels of CRP without hyperlipidaemia showed that treatment with statins reduced the incidence of major cardiovascular events [9]. Moreover, the trial provides only limited and indirect information about the role of CRP. A single CRP measurement equal to or greater than 3 mg/L, in patients with TIA, might play an important role in the selection of patients who are at a higher risk of new cerebral ischaemic events.

More importantly, adding CRP levels to the ABCD² score enhanced the prediction of subsequent cerebral ischaemic events. Patients who are at the highest risk are better identified by combining CRP levels with ABCD² scores. This in turn may lead to the development of new treatment strategies for primary stroke prevention in patients identified as being at risk for developing cerebro-vascular disease. In conclusion, the additional use of CRP levels for the risk assessment in TIA patients improves risk definition in terms of the ABCD² score

alone. Routine CRP measurement should be used in TIA patients who do not have concurrent infection or inflammatory comorbidities and might benefit from more aggressive secondary prevention strategies or from a lowering of CRP levels, which may be achieved either with or without medication [34-37].

Chapter 57

THE GROWING PREVALENCE OF ATRIAL FIBRILLATION, ESPECIALLY ON STROKE UNITS

João Sargento-Freitas and Luís Cunha*
Stroke Unit, Coimbra's University and Hospital Centre

ABSTRACT

Atrial fibrillation (AF) is the most common sustained cardiac rhythm disorder and is associated with a 4- to 5-fold increase in the risk of stroke and systemic embolism. The dominant position of AF in present stroke units may be understood as in line with its high prevalence but also with the functional impairment of strokes caused and increased neurological severity at presentation.

Across the years different series have expressed heterogeneous results on the relative frequency of cardioembolism as etiology of ischemic stroke. Nonetheless, a clear uprising tendency may be observed with an almost two-fold increase in the last 25 years. Many factors concur to this development but mainly the aging of populations. Notably, the relationship of AF with age extends beyond its higher frequency to the greater stroke risk involved. This factor together with the improvement in control of classical vascular risk factors has produced an exponential breakthrough in the presence of AF in current stroke units. Furthermore, despite the efficacy of vitamin K antagonists, fear of hemorrhagic complications along with doubts on “low-risk” patients and difficulty in accessing regular analytical control greatly impaired its adequate usage.

The major factors promoting the ascent of AF are mostly set to worsen in the upcoming years. The new generation of anticoagulants is a new determinant in this equation but their ultimate impact is yet to be ascertained.

INTRODUCTION

Cerebrovascular diseases comprise one of the main causes of mortality and morbidity worldwide. Nonetheless, the precise definition of the etiopathogenic underlying mechanism is

* Corresponding Author's Email: jsargentof@hotmail.com.

crucial to guide acute medical care and, more significantly, the secondary prevention strategy (1-3). Cardioembolism has always been an important source of ischemic stroke, however it has shown quite heterogeneous frequencies throughout different series ranging from 15% to over 40% (1-6). Although many cardiac conditions can account for systemic embolism one pathology arises as the undisputed leader causing ischemic stroke: Atrial Fibrillation (AF). Atrial fibrillation (AF) is the most common sustained cardiac rhythm disorder and is associated with a 4- to 5-fold increase in the risk of stroke and systemic embolism (3). Ultimately, this arrhythmia has been recognized as one of the major medical challenges in modern society and its clinical, social and economic aspects are all set to worsen over the coming decades, especially considering its increasing frequency with age (3, 7).

The dominant position of AF in present stroke units may be understood in line with its high prevalence but also with the clinical features particular to the ischemic strokes caused. In fact, although cardiac emboli can take any size they frequently have larger dimensions than in other causes of stroke (1) leading to more severe strokes with lower frequencies of hospital discharges to asymptomatic patients, greater mortality, as well as higher short-, medium- and long-term recurrence rates (5, 8-10). Moreover, cardioembolic strokes typically present with a sudden onset to maximal deficit (< 5 minutes) which is present in 47-74% of cases and decreased level of consciousness at onset in 19-31% of cases (9, 11-14) both features directly causing higher admission rates to stroke units.

Altogether, cardioembolism and particularly AF, has gradually been assuming a more and more prevalent position in the patients admitted to contemporary stroke units worldwide.

The aim of this chapter is to briefly review the impact of AF in current stroke units as well as analyzing possible trends in its prevalence.

PREVALENCE OF CARDIOEMBOLISM IN STROKE UNITS

Across the years different series have expressed heterogeneous results on the relative frequency of cardioembolism as etiology of ischemic stroke. In western countries a clear tendency can be observed to the uprising presence of AF (figure 1). In the late 80's/early 90's cardioembolism was held responsible for less than 20% of ischemic strokes (15-18). These figures increased to under 30% in the first decade of the 21st century (19, 20) and values of over 30% in the second decade (4, 6).

The comparative studies of Carrera et al. and Arboix et al. both document an almost two-fold increase in the frequency of cardioembolism in the past 25 years (from 17.5% in 1979-1987 to 27.8% in 1996-2003 and 14.6% in 1986-1992 to 27.6% in 1999-2004, respectively)(19, 20). In parallel, AF has also shown a significant increase (from 20.8% to 29.3% in the latter study)(19).

A few conditions may account for this evolution. Firstly and more importantly the indirect effect of population aging. The increment of AF with age is well established with reported frequencies of almost 15% in the population over 80 years old (3, 21-23). Moreover the relationship of age with AF extends to the increased risk of stroke. This data has been translated into clinical recommendations and has motivated a review of previous cardioembolic risk scores. In fact, the relative weight of age (particularly when over 75 years old) has risen in the recently created CHA₂DS₂VASc score and is now considered to be

equivalent to the risk escalation caused by a previous ischemic cerebrovascular event (7). Another factor relates to the worldwide campaigns to monitor and control classic vascular risk factors, such as high blood pressure, dyslipidemia, smoking or elevated blood glucose. The impact of these measures now begin to be visible with a reduction of ischemic events related to those risk factors. This ultimately promotes aging of populations which in turn perpetuates the exponential increase in the relative presence of AF as etiology of stroke. Furthermore, up to a few years ago only one valid strategy stood for stroke prevention: vitamin K antagonists. This class of drugs, albeit its unequivocal efficacy, was massively underused (6, 24-26) mostly due to doubts on “low-risk” patients, fear of hemorrhagic complications and difficulty in accessing regular analytical control(8, 27, 28).

Figure 1. Histogram representing the relative frequency of cardioembolism across different studies. The results are shown chronologically according to the year of publication.

A SINGLE CENTRE EXPERIENCE

To evaluate the frequency of cardioembolism in our centre (a tertiary hospital in Portugal) we performed a crosssectional analysis to all consecutive patients admitted with the diagnosis of ischemic stroke during the year of 2010 (6). Notably, all patients with ischemic stroke are admitted in our centre. We chose to exclude transient ischemic attacks as they are not systematically admitted. The etiology of stroke was defined according to the TOAST criteria (29). In patients with the diagnosis of AF (permanent, persistent or paroxysmal) previous to the stroke we analyzed antithrombotic options.

We had a total of 631 patients admitted due to ischemic stroke. Mean age 73.2 years (SD: 12.4) and 342 (55.2%) male. Cardioembolic stroke was the most frequent with 218 patients (34.5%), small vessel occlusions was documented in 18.2%, large artery atherosclerosis in 25.8%, other causes in 7.0% and the cause remained undetermined in 14.4%. From the patients with cardioembolic stroke 199 (91.3%) were due to, 5 (2.3%) to prosthetic valve, 3

(1.4%) to cardiac insufficiency, 4 (1.8%) a embolic valvulopathy, 2 (0.9%) to acute myocardial infarction and 1 (0.5%) to patent foramen ovale. The frequency of AF in the whole stroke population increased to 32.2% (203 patients) adding 4 patients with AF classified as undetermined due to multiple etiologies.

Among the ischemic strokes caused by AF, the vast majority, (65.3%, 130 patients) had its diagnosis previous to the stroke. From those, only 26.9% (35) were on vitamin K antagonists and only 8.5% (11) showed INR within the therapeutic range (figure 2).

Figure 2. schematic representation of the antithrombotic options in the patients with the diagnosis of AF prior to the ischemic stroke. In grey are represented patients on antiplatelets (63.1%); in stripes patients on vitamin K antagonists outside therapeutic INR range (18.4%); in white those on therapeutic INR range (8.5%).

These results confirm the higher prevalence of cardioembolic stroke reported in recent literature. However, the antithrombotic options observed prior to stroke rise significant concern. In fact, although similar to other series (24, 25) they are contrary to the recent guidelines of the European Society of Cardiology (3) that recommend disconsidering the use of antiplatelet agents as cardioembolic prophylaxis in primary and secondary prevention. The low number of patients with AF and ischemic stroke presenting with therapeutic INR confirms the efficacy of vitamin K antagonist while on therapeutic dosage and is once again a possible sign of under usage of these therapeutic agents.

FUTURE PERSPECTIVES

The clinical, social and economic aspects are all set to worsen over the coming decades³. Looking at the main factors that sustained the ascent of AF in stroke units it is unlikely to presume a change in the upcoming years. One factor seems to promote this above all: age. Populations are expected to grow older in the near future and this will render a continuous increase in relative frequency of AF. On the other hand, one aspect is subject to change: therapeutic approach. Indeed a new generation of anticoagulants has been approved for stroke prevention (30-32). Their improved safety profile has shifted the paradigm of “low-risk” and the absent requirement of periodic analytical control has enhanced access to efficient therapy. Nonetheless concerns remain on their short-acting mechanisms of action and therapeutical approach to patients with stroke whilst taking these medications. We enthusiastically await to see their effect in the relative frequency of AF in the stroke units of the years to come.

Chapter 58

N-TERMINAL PROBRAIN NATRIURETIC PEPTIDE AS A BIOMARKER OF CARDIOEMBOLIC STROKE

Ana Catarina Fonseca^{1,*} and José M. Ferro¹

¹Department of Neurosciences - Neurology,
Santa Maria Hospital, Lisbon, Portugal

ABSTRACT

Even after an extensive etiological investigation in about one third of ischemic strokes it is not possible to establish a cause. A fraction of these strokes could have been due to an episode of paroxysmal atrial fibrillation that was not diagnosed. Studies show that the current available methods to diagnose atrial fibrillation have a low sensitivity. Therefore, it is important to consider new ways to diagnose paroxysmal atrial fibrillation. New methods to diagnose atrial fibrillation include the use of biomarkers. One of the substances that has been pointed as a possible biomarker in this context is the N-terminal of the brain natriuretic peptide (NT-proBNP).

NT-proBNP serum levels in patients with cardioembolic stroke are higher than in patients with non-cardioembolic stroke. Cut-off points of serum NT-proBNP levels with a high sensitivity and specificity for the diagnosis of paroxysmal atrial fibrillation in the first 72 hours after ischemic stroke have been established and analysed in patients in patients with cryptogenic stroke. Measuring NT-proBNP levels in patients with cryptogenic stroke could help to select which patients benefit the most from long term heart rhythm monitorings looking for paroxysmal atrial fibrillation.

Keywords: NT-proBNP, biomarker, paroxysmal atrial fibrillation, diagnosis, stroke

INTRODUCTION

Paroxysmal atrial fibrillation (pAF) is reported to have the same risk to cause ischemic stroke as permanent or persistent atrial fibrillation [1].

* Corresponding Author's Email: catarinagfonseca@gmail.com.

However its often short duration and lack of accompanying symptoms can difficult its diagnosis making it clinically under detected [2]. Due to the importance of diagnosing paroxysmal atrial fibrillation in the context of ischemic stroke all patients should do at least one 12 lead ECG during the etiological workup of stroke, as recommended by both the American Heart Association and the European Stroke Organization [3, 4]. In patients with an undetermined stroke etiology and when a cardioembolic stroke etiology is suspected, it is also recommended to perform a 24 hours ECG recording (Holter) [3, 4]. The 24 hours ECG recording has a higher sensitivity for the diagnosis of paroxysmal atrial fibrillation than a routine 12 lead ECG. In a systematic review [5] the detection rate of paroxysmal atrial fibrillation by a 24-72 hours ECG recording was 4.6%. Serial ECG assessments within the first 72 hours of an acute stroke significantly improve detection of AF [6]. Longer recordings such as with a 7-day ambulatory ECG monitoring using an event-loop recording (ELR) device detected paroxysmal atrial fibrillation in more 6 to 8% of patients after a non-diagnostic 24 hours ECG monitoring [7]. The use of 7 days event-loop recorders at 0, 3 and 6 months after stroke onset detected paroxysmal atrial fibrillation in 14% of patients with an initial negative 24 hours ECG monitoring [5]. Nevertheless in order to register events using this device it is necessary to have the patient's collaboration and periods of asymptomatic atrial fibrillation are therefore not noticed. A Mobile Cardiac Outpatient Telemetry during a period of 21 days in patients with cryptogenic transient ischemic attack or stroke resulted in a paroxysmal atrial fibrillation detection rate of 23% [8].

Currently, about one third of ischemic strokes after a comprehensive investigation are classified as having an undetermined cause. It is possible that a fraction of these strokes named as cryptogenic may have been due to an undetected episode of atrial fibrillation [9]. Due to low sensitivity of the current available methods to detect paroxysmal atrial fibrillation, alternative ways to detect this arrhythmia in cryptogenic stroke have been considered, namely the use of biomarkers. One of the substances that are being studied as possible biomarkers of cardioembolic stroke related to atrial fibrillation is the N-terminal of the brain natriuretic peptide (NT-proBNP).

BRAIN NATRIURETIC PEPTIDE AND N-TERMINAL PROBRAIN NATRIURETIC PEPTIDE

Biomarker is defined as a molecular, biological, or physical characteristic that indicates a specific physiologic state. It is used in clinical practice to identify risk for disease, diagnose disease and its severity, guide intervention strategies, and monitor patients response to therapy [10]. Biomarkers have been progressively recognized as important diagnostic tools. Ideally, a biomarker should be highly sensitive, specific, accessible, accurate, reproducible by an analytical method, cost-effective and have a result that can be easily interpreted by a physician [11].

NT-proBNP is part of a group of natriuretic peptides, phylogenetically conserved along time. Included in this group of peptides are also atrial natriuretic peptide (ANP), natriuretic peptide type C, urodilatin and the *Dendroaspis* natriuretic peptide [12].

The NT-proBNP is initially produced as a prepropeptide of 143 amino acids. This prepropeptide is proteolytic cleaved into a non-active N-terminal fragment composed by 10

amino acids designated proBNP. ProBNP after secreted is divided in two fractions by proteolytic enzymes. These two fractions are BNP that is biological active (aa 77-108) and the N-terminal-proBNP (NT-proBNP) (aa 1-76) without biological activity [13]. BNP and NT-proBNP concentrations can be determined in blood samples [14]. The half-life of NT-proBNP is superior to the half-life of BNP (120 minutes versus 22 minutes) [15]. It is due to this difference in half-life that most essays measure NT-proBNP instead of BNP. Although it was initially isolated in porcine brain in 1988 [16], explaining its designation as brain natriuretic peptide, subsequent experiences showed that it also had a cardiac production [17]. Currently it is considered that the heart is its main production site. In the brain, NT-proBNP is mainly produced in the hypothalamus. The cerebral cortex, thalamus, pons have also been pointed as possible production sites [18]. NT-proBNP in normal situations does not cross the blood-brain barrier [19].

In the heart, NT-proBNP can be produced by both atria and ventricles [20]. After being produced NT-proBNP is mainly secret in “bursts”. Its storage in granules is minimal [21]. NT-proBNP seems to be more present in the atria rather than in the ventricles. However, due to the larger ventricular mass, 70% of all NT-proBNP is produced by the ventricle in normal conditions [22]. The main stimulus for the synthesis and excretion of NT-proBNP in the heart is myocytes stretching, mainly in the context of volume [23] or cardiac pressure overload [24]. After stretching there is a rapid activation, within hours, of NT-proBNP gene expression [25]. Certain hormones (catecholamines, angiotensin II and endothelin-1) may stimulate the production of NT-proBNP through paracrine or endocrine mechanisms. [26]

BNP acts by an endocrine mechanism. It has an important role in the cardiovascular homeostatic regulation and in volume control. Its biological effects include natriuresis, diuresis, vasodilatation, inhibition of the renin-angiotensin-aldosterone axis and of the sympathetic nervous system [27]. In the heart, BNP has a lusitropic and antifibrotic effect [28]. NT-proBNP is cleared from circulation through the kidney by direct filtration and passive excretion [29].

Serum NT-proBNP and BNP levels in healthy individuals increase with age and are higher in women than in men [30]. Ninety percent of young adults have NT-proBNP levels below 70 pg/mL [31]. BNP plasmatic levels correlate with left ventricular mass. NT-proBNP is currently used as a marker of left ventricular dysfunction and of prognosis in patients with congestive heart failure and in acute ischemic heart disease [32]. High NT-proBNP serum levels have been found in patients with renal failure, anemia, acute pulmonary embolism, pulmonary hypertension, sepsis, mitral and aortic regurgitation and dysrhythmias such as atrial fibrillation [33, 34].

Without structural heart disease, patient with lone paroxysmal atrial fibrillation have increased NT-proBNP [35]. Increased plasmatic levels of NT-proBNP have been found in patients with permanent or paroxysmal atrial fibrillation with preserved left ventricular systolic function [36]. A return to baseline of NT-proBNP values after electric cardioversion of atrial fibrillation to sinus rhythm was documented [37]. NT-proBNP has been shown to be a remarkable predictor of incident AF in the general population, independently of any other previously described risk factor [38]. Recent studies that suggest that NT-proBNP is a predictor of atrial fibrillation following cardiac surgery [39-41] and successful cardioversion [42].

There is currently no established explanation for the increase of NT-proBNP in the context of atrial fibrillation. In the isolated atria tissue of rat, alpha1-adrenergic stimulation

with phenylephrine induces genetic expression of BNP [43]. It is unknown if alpha1-adrenergic stimulation results in an increase in the synthesis of NT-proBNP in patients with atrial fibrillation. A study that analysed human right atrial tissue found that persistent atrial fibrillation was associated to a high expression of proBNP mRNA. However, patients with paroxysmal atrial fibrillation did not have changes in proBNP gene expression [44].

NT-PROBNP IN ACUTE ISCHEMIC STROKE

Although NT-proBNP presence was first described in the brain tissue, information regarding NT-proBNP in ischemic stroke is small. Some studies showed an acute increase in NT-proBNP and BNP serum levels in acute ischemic stroke [19, 45-53]. These studies initially aimed to determine if NT-proBNP or BNP could be used as prognostic markers of acute ischemic stroke along with other markers of myocardial injury such like troponins. It was suggested that it could be used as a marker of long term bad prognosis. It was then noticed that patients with acute ischemic stroke tended to have high levels of NT-proBNP and BNP. Four possible explanations for the increase of NT-proBNP and BNP during acute ischemic stroke were initially proposed in these studies:

- 1 Patients with acute ischemic stroke frequently have several vascular risk factors and may have an associated acute or chronic heart failure. Therefore, the increase in NT-proBNP levels could be due to ventricular dysfunction;
- 2 The increase in NT-proBNP levels could be due to atrial fibrillation. Atrial fibrillation is a major risk factor for ischemic stroke and a known cause of NT-proBNP increase;
- 3 As the brain is a site of BNP and NT-proBNP production, although it only produces a small amount of these peptides it is possible that after an acute ischemic lesion there is a release of BNP and NT-proBNP that is measurable in the serum.
- 4 BNP has an inhibitory action in the central and peripheral sympathetic nervous system. BNP could be increased in acute ischemic stroke as a response to the increase sympathetic activity that occurs after stroke

Serum NT-proBNP levels were further analysed in patients with acute ischemic stroke [54]. Patients with cardioembolic ischemic stroke were found to have mean concentrations of NT-proBNP which were significantly higher than in patients with non-cardioembolic stroke. An association between serum NT-proBNP levels and the extent or location of ischemic stroke or blood pressure measurements was not found. NT-proBNP was found to have a good accuracy for the diagnosis of cardioembolic stroke in general (Area under the curve (AUC) of 0.77 ± 0.12) and a very good accuracy for the diagnosis of cardioembolic stroke related to atrial fibrillation (AUC of 0.92 ± 0.06). For the diagnosis of cardioembolic stroke related to atrial fibrillation, two cut-off points of NT-proBNP with a high sensitivity and specificity were determined from the analysis of receiver operating characteristic curves - 265.50 pg/mL (sensitivity 94.4%, specificity 72.9%, positive predictive value 56.6% and negative predictive value 97.2%) and 912.0 pg/mL (sensitivity 55.5%, specificity 97.9%, positive predictive value 90.9% and negative predictive value 83.9%).

Most of the studies that measured NT-proBNP as a biomarker of cardioembolic stroke measured this peptide during the first 12 to 24 hours after the onset of symptoms of ischemic stroke. However, there was no clear evidence that this was the best time to measure it. In a study that aimed to determine NT-proBNP levels within 24, 48 and 72 hours after ischemic stroke and to analyse its variation [55], in all included stroke patients and in those with cardioembolic and noncardioembolic stroke (including undetermined causes), values of NT-proBNP were highest in the first 24 to 48 hours after ischemic stroke with no statistically significant difference between those two time points and had a statistically significant reduction 72 hours after stroke onset.

However, the value of the area under the curve for the diagnosis of cardioembolic stroke related to atrial fibrillation was similar in the three time points. This suggested that the measurement of NT-proBNP levels with the first 72 hours after ischemic stroke had a similar diagnostic accuracy for the diagnosis of cardioembolic stroke. The form of release of NT-proBNP from the heart may explain this time course. Normally atrial and ventricle myocytes express BNP genes that code for ProBNP. ProBNP is stored in atrial and ventricular granules. In the first two days following stroke, the precursor molecules, pre-produced proBNP that are stored in atrial myocytes are secreted as BNP and NT-proBNP after the haemodynamic effects of atrial fibrillation or atrial flutter [56]. This causes the high levels of NT-proBNP that are observed. At Day 3, NT-proBNP levels may start to decrease due to a depletion of stored proBNP.

NT-proBNP cut-off levels for the diagnosis of atrial fibrillation were further validated in patients with cardioembolic stroke and in patients' with an initial cryptogenic stroke that were followed prospectively. Among 264 ischemic stroke patients NT-proBNP serum levels were measured within 72 hours of stroke onset [57]. In cryptogenic stroke patients, 24 hour Holter monitoring was used to look for pAF within the first week, three and six months after admission. First, patients with a defined etiology were used to construct a Receiver Operating Characteristic (ROC) curve for the diagnosis of AF. From this curve, the sensitivity and specificity of pre-established cut-off points for the diagnosis of atrial fibrillation were calculated. The cut-off points were then evaluated in patients with cryptogenic stroke. The Area Under the Curve of the Receiver Operating Curve of NT-proBNP for the diagnosis of AF was 0.91, 95% CI (0.87-0.95).

Using multivariate analysis NT-proBNP was independently associated to AF (OR – 2.65, 95% CI 1.57-4.45; $p < 0.0001$), after adjusting for age, sex, left ventricular hypertrophy, atrial dilatation and systolic dysfunction. 80 patients had a cryptogenic stroke. In 17, pAF was found during follow-up.

In these patients, the AUC for the diagnosis of paroxysmal atrial fibrillation was 0.83. The cut-off point of 265.5 had a sensitivity of 88.2% and a specificity of 61.9%. The cut-off point of 912 pg/mL had a sensitivity of 47.1% and a specificity of 88.9%. NT-proBNP had a good accuracy to predict pAF in patients with cryptogenic stroke. NT-proBNP levels at the time of stroke onset were helpful to identify paroxysmal atrial fibrillation in the follow-up of patients with an undetermined stroke etiology.

Further studies are needed to support and validate the defined cut-offpoints. A clinical trial of anticoagulation in cryptogenic stroke patients with increased NT-proBNP could be helpful.

CONCLUSION

In patients with cryptogenic stroke, detecting paroxysmal atrial fibrillation is particularly important as it changes the therapeutic decision, leading to the prescription of anticoagulants instead of antiplatelet agents. Cryptogenic stroke patients are several times submitted to costly electrophysiological investigations. NT-proBNP measurements could be helpful to guide or eliminate further electrophysiologic monitoring in patients with cryptogenic ischemic stroke. In patients with cryptogenic stroke with uneventful echocardiograms an increase in NT-proBNP may point to the presence of paroxysmal AF and lead to further cardiac electrophysiological investigations.

Chapter 59

FROM CRYPTOGENIC STROKE TO PAROXYSMAL ATRIAL FIBRILLATION

Gustavo Cordeiro*, Cristina Duque and Luís Cunha

Stroke Unit, Neurology Department,
Coimbra's Hospital and University Centre, Portugal

ABSTRACT

Ischemic stroke, the most prevalent type of stroke is, frequently, the result of large artery atherosclerosis, small vessel disease or cardioembolism.

However, the etiology remains unclear in up to 25 to 30% of stroke patients, despite a complete initial work-up. In some of them, paroxysmal atrial fibrillation (PAF), a condition that carries an equally high stroke-risk as persistent or permanent atrial fibrillation, is a likely contributing cause.

There are some clinical characteristics but also imaging, electro and ecocardiographic findings that are suggestive of a cardiac source of embolism. In this chapter we will discuss in detail the features that support the suspicion of a cardioembolic stroke specifically due to PAF.

Different kind of noninvasive and invasive detection methods have been developed in the last few years, to monitor cardiac rhythms for long time periods. They are, and probably will be in the near future, an important tool to identify PAF in cryptogenic stroke patients. It remains to be established, however, the criteria that should be used to select the patients that are more likely to benefit from a closer cardiac monitoring.

INTRODUCTION

Ischemic stroke, the most prevalent type of stroke, is caused by thrombotic or embolic occlusion of cerebral arteries. Embolism, in turn, can result from an arterial or cardiac source. The most relevant etiopathogenic subgroups, as reflected by the TOAST classification [1], are large artery atherosclerosis, cardioembolism and small vessel disease.

* Corresponding Author's Email: gustavo.mtato@gmail.com.

In many patients, clinical history, physical examination and routine diagnostic tests (electrocardiogram, cervical ultrasonography and transcranial doppler, neuroimaging studies, blood analysis) are enough to easily determine the presumed etiology [2].

Some stroke patients are not adequately investigated. In those with an incomplete evaluation during hospitalization, the overall cumulative death rate (25,5% within one year) is highest when compared with those with undetermined etiology despite extensive work-up. [3].

The identification of the etiology and mechanism involved in ischemic stroke is a great challenge for the clinician but is essential for planning adequate secondary prevention. Nevertheless, a relevant number of patients (25 to 30%) (4) is considered to have a stroke of unknown cause, despite full investigation – the so-called cryptogenic stroke .

Although there is a considerable disagreement among experts regarding the extent of cardiac testing in stroke patients [5], searching for a cardiac etiology is a relevant, sometimes determinant, part of the investigation. In the presence of a cryptogenic stroke, one of the major suspects is paroxysmal atrial fibrillation (PAF) and a presumed cardioembolism should not be excluded just because we can not find any structural cardiac abnormality.

In fact, several small studies of long-term cardiac monitoring have suggested that 6,4% to 21,3% of patients with ischemic stroke of unknown cause may have PAF as a likely contributing cause [6].

PAROXYSMAL ATRIAL FIBRILLATION (PAF)

AF is an atrial tachyarrhythmia characterized by predominantly uncoordinated atrial activation with consequent deterioration of atrial mechanical function [7].

It is the most common sustained rhythm disorder and is, probably, a self-promoting disease in which progressive electrophysiologic remodeling and anatomical changes in the atria play a role in the perpetuation of AF [8]. The pathogenesis is thought to involve an interaction between initiating triggers, often in the form of firing ectopic foci located inside one or more pulmonary veins and an abnormal atrial tissue substrate capable of maintaining the arrhythmia [9]. It is, therefore, understandable that PAF frequently evolve to persistent or permanent AF . PAF prevalence is estimated to comprise between 25 and 62% of cases of AF seen by practitioners in both hospital and primary care setting [10] . The first symptomatic episode may follow many silent ones [11] and thus, reported prevalence is, probably, underestimated as most epidemiological studies depend on symptomatic episodes [10] and asymptomatic AF is common.

On the other hand, PAF carries an equally high stroke-risk as persistent or permanent AF [12] and the frequency and duration of PAF are thought to be associated with that risk [13]. In the TRENDS study [14], a prospective, observational study enrolling patients with ≥ 1 stroke risk factor (heart failure, hypertension, age ≥ 65 years, diabetes, or prior thromboembolism) receiving pacemakers or defibrillators, it was noticed that an atrial tachycardia/AF burden ≥ 5.5 hours on any of 30 prior days appeared to double thromboembolic risk.

In the last few years, different kind of noninvasive and invasive detection methods have been developed: event recorders, external loop recorders/mobile cardiac outpatient telemetry (MCOT), implantable loop recorders, implantable therapeutic devices.

With the improvement in technology it is now possible to perform cardiac monitoring for long periods of time. Furthermore, these devices are so sensitive that it allows the detection of rare, very brief, asymptomatic episodes of AF (often referred to as occult AF) that likely would have eluded detection using standard in-patient telemetry or Holter monitoring [15].

PAF was detected in 27 of 156 (17.3%) cryptogenic stroke patients using a 21-day mobile cardiac outpatient telemetry [16].

In the SMART registry [17] approximately 1 in every 9 patients with cryptogenic ischemic stroke was found to have new PAF within 30 days.

The CRYSTAL AF trial [4] was a randomized prospective single-center cohort study to evaluate a implantable subcutaneous cardiac monitor to long-term monitoring for AF detection in patients with cryptogenic stroke. The preliminary data was published in July/13. The cardiac event recorder was eligible for implantation in approximately one third of patients and PAF was detected in 27,3% of these cryptogenic stroke patients. These results should be cautiously interpreted, given the notorious small number of eligible patients.

Until this precise moment some questions remain partially unanswered when facing a cryptogenic stroke:

- Which parameter/combination of parameters rise suspicion of PAF involvement in stroke etiology?
- Which group of patients should be submitted to close cardiac monitoring after a cerebral ischemic event of unknown cause?

In this article we will review the main features associated with stroke due to paroxysmal atrial fibrillation.

FEATURES THAT SUPPORT THE SUSPICION OF A CARDIOEMBOLIC ETIOLOGY DUE TO PAF IN CRYPTOGENIC STROKE

A – Absence of a More Plausible Etiology for the Stroke

A1 – Exclusion of a «vascular etiology»

After a complete work-up, a paroxysmal AF etiology for the ischemic stroke should remain the first suspect in the absence of a more plausible etiology for the event, specially a «vascular etiology». We use the same definition reported by Laurent Suissa et al. [18] and so, for «vascular etiology» we mean cervical and/or cerebral symptomatic atherosclerosis (intra and/or extracranial stenosis $\geq 50\%$), clinico-radiological lacunar syndrome or other vascular cause for the stroke (dissection, etc).

Whether a carotid stenosis of less than 50% is a marker of atherosclerosis or also a cause of stroke [19], specially in the presence of heterogeneous and irregular plaques, is a matter of debate.

A2 – Exclusion of Other Causes

Stroke may result from inflammatory diseases, migraine and other vasoconstrictive conditions, connective tissue disorders, coagulopathy, infection or malignancy. These entities should be considered and excluded.

B - Clinical Features

Strokes due to cardiac embolism are generally associated with poor prognosis, short and long-term recurrence, higher in-hospital mortality and a higher index of fatal recurrence versus other causes of stroke [5].

Atrial fibrillation, in particular, an age-related condition, is associated with a greater volume of more severe baseline hypoperfusion, leading to higher infarct growth and worse stroke outcomes [20]. When an ischemic stroke is under investigation we should keep in mind that a cardiac source typically produces any kind of non-lacunar syndrome presentation. That is, a total or partial anterior circulation syndrome (TACS or PACS) or a posterior circulation one (POCS). Clinical noncortical lacunar strokes and proven lacunar infarcts are etiologically and pathophysiologically distinct from other infarcts and are caused, usually, by cerebral small vessel disease [21]. Gan et al. reported that 75% of patients with radiological confirmed lacunar infarction had a lacunar mechanism of infarction. Cardioembolism was presumed in only 5% of these patients [22]. Although a sudden onset to maximal deficit (less than 5 minutes) may suggest a cardiac source of emboli, it is not specific, as this pattern overlaps with other stroke causes [23]. A rapid regression of the symptoms occur in 4,7 to 12% of the cardioembolic stroke patients which may be due to distal migration of the embolus and recanalization of the vessel [2, 24].

Isolated aphasia was suggested to be an independent sign of AF in patients with a transient ischemic attack (TIA) or PACS [25]. Visual-field abnormalities and neglect are also clinical features that support the suspicion of an embolic source [26].

In the vertebro-basilar circulation we may think of embolism in the presence of Wallenberg syndrome (usually due to an occlusion of the postero-inferior cerebellar artery), top of basilar artery syndrome or a clinical deficit in the territory of the posterior cerebral artery. Multilevel infarcts and cerebellar infarcts are also more common in cardiac source of emboli [2]. Seizures at onset are not specific of cardioembolism but are more likely to occur from embolism to distal cortical brain tissue compared to small vessel disease infarcts on deep locations [23].

Another feature that may be related with cardiac embolism is the detection of previous chronic treatment with antiarrhythmic drugs. We found that association (Table 1) in our cryptogenic stroke patients in which a PAF was identified during a 6-months follow-up period (unpublished data). We speculate that this finding may be related with clinical previous detection of that arrhythmia but, for some reason, the decision was not to treat with anticoagulants.

C – Cardiac Findings

C1- Electrocardiography

Ischemic stroke patients usually perform a baseline ECG in the emergency setting and later one, sometimes more, during their stay in the hospital. Those who are admitted in the stroke unit are under continuous cardiac monitoring for some days and nurses should be trained in the detection of any kind of atrial arrhythmia. We also recommend to check for all available ECG/Holter monitoring carried out before the stroke.

Table 1. Baseline characteristics of cryptogenic stroke patients registered between June 2010 and December 2012 in our stroke unit. During a 6-months follow-up period PAF was identified in 31,9%

	All patients (n=113)	AF unidentified (n=87)	AF identified (n=36)	<i>p value</i>
Male sex	53 (46,9%)	40 (51,9%)	13 (36,1%)	0.116
Patients > 75 years	54 (47,8%)	29 (37,7%)	25 (69,4%)	0.002
Hypertension	91 (80,5%)	59 (76,6%)	32 (88,9%)	0.125
Diabetes mellitus	30 (26,5%)	19 (24,7%)	11 (30,6%)	0.510
Dyslipidemia	59 (52,2%)	42 (54,5%)	17 (47,2%)	0.468
Overweight	11 (15,3%)	7 (15,6%)	4 (14,8%)	0.1
Alcoholism	10 (8,8%)	7 (9,1%)	3 (8,3%)	1.0
Current or past smoker	36 (31,9%)	9 (11,7%)	1 (2,8%)	0.165
Congestive heart failure	5 (4,4%)	2 (2,6%)	3 (8,3%)	0.325
Coronaryopathy	13 (11,5%)	8 (10,4%)	5 (13,9%)	0.752
Arterial peripheral vascular disease	4 (3,5%)	2 (2,6%)	2 (5,6%)	0.591
Arterial systemic disease	33 (29,2%)	23 (29,9%)	10 (27,8%)	0.820
Previous medication: digoxin	2 (1,8%)	0	2 (5,6%)	0.1
Previous medication: sotalol, amiodarone or CCB	10 (8,8%)	2 (2,6%)	8 (22,2%)	0.002
Previous medication: beta-blockers	13 (11,5%)	6 (7,8%)	7 (19,4%)	0.110
Cerebrovascular US: slight or no atherosclerosis	94 (83,2%)	61 (79,2%)	33 (91,7%)	0.99
Left atrial “smoke” in TEE	5 (9,4%)	1 (2,7%)	4 (25%)	0.025
Left atrial enlargement	27 (42,9%)	9 (22,5%)	18 (78,3%)	<0.001
ECG: SVES	13 (11,5%)	9 (11,7%)	4 (11,1%)	1
Holter ECG: frequent/ very frequent SVES	46 (40,7%)	35 (45,5%)	11 (30,6%)	0.133
Cortical stroke	95 (85,6%)	61 (79,2%)	34 (100%)	0.002
Hemorrhagic transformation	13 (11,5%)	6 (7,8%)	7 (19,4%)	0.110
CT spontaneous hyperintensity	23 (20,4%)	17 (22,1%)	6 (16,7%)	0.506
Previous cortical stroke	34 (30,1%)	14 (41,2%)	20 (58,8%)	<0.001
Previous and current cortical stroke	96 (85,7%)	35 (100%)	61 (79,2%)	0.004
New stroke during follow up	7 (6,2%)	3 (3,9%)	4 (11,1%)	0.207

X² tests were used to compare variables; variables with statistical significance ($p < 0.05$) in bold.
Preliminary data.

CCB: calcium channel blockers; US: ultrasonography; TEE: transesophageal echocardiogram; SVES: supraventricular extrasystoles.

Serial ECG performed in the first 72 hours seems to increase detection almost 3-fold, with half of the new-onset AF being detected on initial ECG and the rest on serial ECG assessments [27].

The 24-hour ECG recording (Holter monitoring) can also play a role in PAF detection. Tagawa et al. reported that PAF was newly identified in 8,4% of stroke patients using this diagnostic testing [28].

The presence of premature atrial complex on ECG was identified and suggested as an independent predictor of PAF detection [16]. In patients with acute ischemic stroke, frequent atrial premature beats ($\geq 70/24$ hours) are a marker for individuals who are at greater risk to develop or have paroxysmal AF [29].

Paroxysmal supraventricular tachycardia was recently proposed [30] as an independent risk factor for ischemic stroke. Whether this risk is related with a higher susceptibility to develop paroxysmal atrial fibrillation is unknown.

C2- Echocardiography

In our own study, left atrial dilation (Figure 1) was strongly associated with paroxysmal atrial fibrillation. The same occurred with spontaneous echo contrast (SEC) in left atrium (LA) and/or left atrial appendage (LAA), also known as «smoke», a relatively frequent finding on transesophageal echocardiography (TEE) but rarely detected on transthoracic echocardiography (TTE) [31], and known to be associated with conditions favoring stasis of left atrial blood (32) (Figure 2).

Figure 1. Transthoracic echocardiography displaying a left atrial (LA) dilation (courtesy of Rui Martins, MD, Cardiology Department).

Figure 2. Left atrial spontaneous echocontrast finding (*) in transesophageal echocardiography (courtesy of Rui Martins, MD, Cardiology Department).

Multiple studies have demonstrated that the presence of LA and LAA SEC is a risk factor for the development of local thrombus [33]. Patients with nonvalvular atrial fibrillation with SEC have both, a significantly higher risk of developing stroke or other embolic events, and reduced survival [34].

The predilection for thrombus formation in the LAA has been well described and the ability of transesophageal echocardiography (TEE) to detect them has been established (35, 36). The pathogenesis of LAA thrombus formation is not fully elucidated but is likely to result from stagnation within the long, blind ended trabeculous pouch [37].

A reduced left ventricular ejection fraction was also suggested to be an independent predictor of PAF detection [16]. Other parameters have been proposed as quantitative surrogate parameters of elevated thromboembolic risk in patients with PAF. LAA function, measured by LAA ejection fraction and LAA flow velocity were impaired in patients with cardioembolic stroke caused by PAF, even if TEE was performed during a normal sinus rhythm [38].

D- Neuroimaging Findings

Noncontrast computed tomography is the most frequently diagnostic modality used in the evaluation of acute stroke in many hospitals, despite the widespread availability of MRI [39].

Figure 3. Cortico-subcortical ischemic dissemination in time and space: a previous cortico- subcortical infarct in the right hemisphere and a more recent one, on the other side (brain CT-scan).

Figure 4. Brain CT-scan: hemorrhagic transformation of an ischemic lesion due to a right MCA occlusion.

Figure 5. Brain CT-scan: Spontaneous hyperdensity in the M1 segment of the left middle cerebral artery.

Cardiac emboli travel through the intracranial circulation and often occlude middle-large size arteries. The identification of cortical involvement is characteristic of an embolic mechanism [5]. A distal cortical «wedge» appearance might be the pattern of infarction seen on CT scan or MRI [40]. An embolic event may also have a scattered pattern of infarction, that suggest an embolus that fractured and shattered into several pieces in the downstream vascular territory [23]. Single cortico-subcortical lesions or simultaneous strokes in different arterial territories, especially if bihemispheric, combining anterior and posterior circulation or concurrent systemic embolism are highly suggestive of cardioembolism [41-43].

The presence of previous cortico-subcortical infarcts in the same or other territories, detected during the evaluation of the most recent stroke is also highly suggestive of a cardiac source (Figure 3). Hemorrhagic transformation of infarction (HTI), usually asymptomatic, is a recognized natural consequence of cerebral infarction, occurring in up to one third of stroke patients [44]. Those who experience hemorrhagic transformation are more likely to have cardioembolic stroke [45] (Figure 4), particularly when embolism results in major arterial occlusion and failure of collateral flow [46].

It is plausible that delayed spontaneous recanalization achieved beyond 6-hour time window may increase the risk of hemorrhage in these patients [47]. Although unspecific, a

hyperdense artery sign on CT (Figure 5) can be seen in the presence of an acute intracranial embolus, a phenomenon that is well known and has been extensively documented.

Large middle cerebral artery (MCA) infarction is a frequent finding in patients with atrial fibrillation [48]. In the HAEST study [49] they represented 15% of all stroke patients with that rhythm disorder. In almost half of them a hyperdense middle cerebral artery sign (HMCAS) was noticed. It was recently suggested [50], by the histopatologic analisys of the thrombus, that HMCAS and the correspondent gradient-echo MRI blooming artifact (BA) may reflect the red blood cell content (RBC). In other words, those imagiological signs are present when the thrombus is RBC-dominant, and the absence of HMCAS or BA may indicate fibrin-predominant occlusive thrombi. Features that support the suspicion of cardioembolism due to PAF are summarized in Figure 6.

Figure 6. Ischemic stroke: clinical characteristics, imaging, electro and echocardiographic findings suggestive of a cardiac source of embolism due to PAF.

Figure 7. Stroke of unknown etiology : decision flowchart regarding cardioembolism.

CONCLUSION

Atrial fibrillation is an old arrhythmia involved in a recent growing epidemic [51], mainly due to its age-related incidence. Clinicians that treat stroke patients should be aware that cryptogenic stroke due to PAF is a frequent condition. There are important informations that can be transmitted by a detailed medical history, physical and neurological examination, cardiac work-up, ultrasonography and neuroimaging. There is a new era of new devices that can monitor cardiac rhythms for long periods. Should we use them in every patient who has a stroke of unknown cause? Probably no, we say. Instead of an aggressive investigation in every patient, we prefer a sequential approach (Figure 7) in order to select those that must be closely monitored after a complete but negative initial work-up.

A validated score that helps us to identify these patients is needed.

Chapter 60

NOVEL ORAL ANTICOAGULANTS FOR STROKE PREVENTION IN ATRIAL FIBRILLATION

Vassilis Vassiliou^{1,*}

¹Department of Cardiology, Royal Brompton Hospital, London and Imperial College
London, UK

ABSTRACT

Atrial fibrillation (AF) is the most common sustained cardiac arrhythmia, affecting 1-2% of the general population. The prevalence of AF increases with age and with a growing aging population it is expected to double over the next five decades. AF poses a significant risk factor for stroke, currently conferring a five-fold risk, with one in five strokes attributed to this common arrhythmia. Furthermore, strokes relating to AF are likely to be more debilitating than non-AF related strokes. This causes increased morbidity and mortality and leads to increased physical and psychological distress for the affected patients and their families; as well as additional cost to the community. Preventing stroke in patients with AF is therefore of paramount importance. Over the last few decades the benefit of anticoagulation in patients with AF has been increasingly understood and gained popularity. This is usually achieved with oral vitamin K antagonists, most commonly warfarin. However, novel oral anticoagulants (NOACs) have advantages over warfarin and might provide an alternative to this therapy. This chapter discusses the NOACs dabigatran, rivaroxaban and apixaban and their evidence-based role in anticoagulation for patients with AF.

INTRODUCTION

Atrial fibrillation (AF) is the most common sustained cardiac arrhythmia, affecting 1-2% of the general population [1]. Its prevalence increases significantly with age and is expected to double in the next five decades, reaching ten million in the US by 2050 [2]. Among people younger than 50 years of age the prevalence of AF is less than 0.5%, while this increases by

* Corresponding Author's Email: vassiliou@doctors.org.uk.

up to thirty-fold for people over 80 years old, reaching 5-15% [3]. Furthermore, other patient populations (e.g., those with a permanent pacemaker) have a higher prevalence, often in excess of 30-35% [4, 5].

Atrial fibrillation was once considered a “benign” arrhythmia [6] as it can be associated with mild or no symptoms. However, it is now well understood that, even in the absence of symptoms, if left untreated AF can cause significant morbidity and death [7]. It confers a doubling in death rate, a five-fold increase in the risk of stroke, increased hospital admissions, impaired exercise capacity, reduced quality of life and tachycardia-induced cardiomyopathy leading to heart failure.

WHY DO PATIENTS WITH AF HAVE A HIGHER RISK OF STROKE AND WHY IS THERE A NEED FOR ANTICOAGULATION?

The cause of strokes and transient ischemic attacks (TIA) in patients with AF was long believed to be thrombus formation in the left atrium and particularly in the left atrial appendage (LAA), with resulting fragmentation and dispersion in the arterial circulation. For up to 90% of patients with non-valvular AF in whom thrombus is identified, it is in the LAA [8]. With its long and tubular structure and a narrow junction with the atrium, the LAA is anatomically prone to hemodynamic stasis [9]. Coupled with its AF-associated dysfunction as a result of reduced peak emptying flow velocities, this is the major contributor for thrombus formation. It is now understood however that thrombus formation in the LAA is not the sole reason for stroke. Up to 25% of patients with high-risk AF could have other atherothrombotic mechanisms contributing to the increased stroke risk [10] making appropriate anticoagulation the most important treatment for reducing stroke and TIA risk in patients with AF.

WARFARIN VS. ANTIPLATELET AGENTS IN AF

Aspirin Use in Stroke Prevention in Patients with AF

With an increased understanding of the pathophysiology of stroke in AF in the last two decades, it has been appreciated that antiplatelet therapy alone is insufficient to significantly reduce the risk of stroke and TIA. Aspirin provides a 20% relative risk reduction in the incidence of stroke, [11] with a 0.5-1% risk of major bleeding [12]. Warfarin on the other hand offers a relative risk reduction of over 60% [11]. Compared to placebo this corresponds to an absolute benefit of 2.7% per year. In practice therefore, for every 37 patients with AF taking warfarin, one ischemic stroke is prevented annually. This also translates into a 26% relative risk reduction in all-cause mortality when compared to placebo [11], making warfarin an obvious recommendation for stroke prevention.

Dual Antiplatelet Therapy for Stroke Prevention in Patients with AF

The AF Clopidogrel Trial with Irbesartan for prevention of Vascular Events (ACTIVE) W study [13] investigated whether dual antiplatelet therapy with concurrent use of aspirin and clopidogrel provides the same benefit as warfarin in stroke prevention in patients with AF. Patients with AF and at least one risk factor for thromboembolic disease were randomized to receive either aspirin 75mg-100mg daily plus clopidogrel 75mg daily, or warfarin (aiming for a target International Normalized Ratio [INR] of 2.5). The combined endpoint of stroke, embolism, myocardial infarction (MI) and vascular death was reached in 5.6% of patients on aspirin and clopidogrel and 3.9% in patients taking warfarin (the relative risk ratio was 1.44, 95% confidence interval [CI]=1.18-1.76, $p=0.0003$), supporting the superiority of warfarin over dual antiplatelets and necessitating this trial to be halted early.

The risk of intracranial hemorrhage (the most problematic side-effect of warfarin) usually occurs with a supra-therapeutic INR ≥ 3.5) highlighting the importance of maintaining an appropriate anticoagulation level and regular monitoring. Achieving this can however be very difficult for some individuals who therefore spend a lot of time outside therapeutic range. Such individuals are at increased risk both from bleeding when the INR is too high and ischemic stroke when it is too low. The difficulty in establishing predictable and continuous anticoagulation remains the main drawback of using warfarin and an area where novel oral anticoagulants (NOACs) could prove to be superior.

THROMBOEMBOLIC RISK STRATIFICATION IN PATIENTS WITH AF

The anticoagulation practice for patients with AF has changed significantly over the last decade, particularly with the awareness that thromboembolic risk can vary significantly between individuals. The benefits of anticoagulation should therefore be weighed against the risk of thromboembolism before this is initiated. Various risk stratification scores have been used to predict thromboembolic risk in AF but the two most widely accepted are the established CHADS₂ and the more recently introduced CHA₂DS₂-VASc; where points are allocated according to the risk profile of each patient (Table 1).

The CHADS₂ score is a useful, simple and rapid scoring system for initial assessment of thromboembolic risk: patients can be categorized to low risk (score =0), medium risk (score =1) and severe risk (score ≥ 2). It has been validated by many studies and despite some recently recognized limitations, it still features in many international guidelines [1, 14-17]. The current guidance from the American College of Chest Physicians (ACCP) published in 2012 [15] for example recommends oral anticoagulation for patients at medium or high risk with CHADS₂ ≥ 1 . For patients in this group who are intolerant or unwilling to consider oral anticoagulation, dual therapy with aspirin and clopidogrel is recommended. This represents a change from the 2008 guidance [18] from the same college where anticoagulation was only recommended for patients with a CHADS₂ score ≥ 2 , acknowledging that even in this medium risk group (CHADS₂=1) the benefits of anticoagulation outweigh the associated risk.

However, further data have also emerged [19] on what were previously regarded as less well-validated risk factors for stroke, namely vascular disease, female gender and age

between 65 and 74 years. The CHA₂DS₂-VASc score incorporated these risk factors, allowing for an even more detailed and accurate estimated stratification of the annual risk of stroke (Table 2) for patients with AF [20]. Furthermore, the system can identify certain categories of patients (e.g., females or patients with peripheral vascular disease or coronary disease) who remain at increased risk of stroke but who would not have been identified using the CHADS₂ score alone.

Table 1. Shows how the two most commonly used stroke risk scoring systems can be calculated

CHADS ₂	Condition	Points allocated	CHA ₂ DS ₂ -VASc	Condition	Points allocated
C	Congestive heart failure or left ventricular (LV) dysfunction with ejection fraction (EF) ≤40%	1	C	Congestive heart failure or left ventricular (LV) dysfunction with ejection fraction (EF) ≤40%	1
H	Hypertension	1	H	Hypertension	1
A	Age ≥75	1	A ₂	Age ≥75	2
D	Diabetes	1	D	Diabetes	1
S ₂	Transient ischemic attack (TIA), stroke or other thromboembolism	2	S ₂	Transient ischemic attack (TIA), stroke or other thromboembolism	2
			V	Vascular disease (e.g., peripheral artery disease, myocardial infarction, aortic plaque)	1
			A	Age 65-74	1
			Sc	Sex category i.e., female	1

CHADS₂ has a maximum of six points and CHA₂DS₂-VASc a maximum of nine points, where more points equates to higher thromboembolic risk

Currently, in accordance with the European Society of Cardiology (ESC) guideline [1], any patient with a CHA₂DS₂-VASc score ≥2 should be considered for anticoagulation, as the 2.2% risk of stroke per annum is less than the risk associated with anticoagulation. Furthermore, anyone with a CHA₂DS₂-VASc score =1 should also be considered for either oral anticoagulation or aspirin therapy. The guidance suggests however that oral anticoagulation would be the preferred option even for these patients with a relatively low risk of stroke. Only for patients with the absolute minimum risk of stroke and a CHA₂DS₂-VASc score =0 is there no benefit from oral anticoagulation as the benefit of anticoagulation does not exceed its associated risk. For such patients either aspirin or no treatment at all could be offered in accordance with the ESC recommendation.

Table 2. Using the CHA₂DS₂-VASc score an annual adjusted risk score for stroke can be estimated, and the benefits of anticoagulation considered

CHA ₂ DS ₂ -VASc score	Risk (annual adjusted risk)
0	0%
1	1.3%
2	2.2%
3	3.2%
4	4.0%
5	6.7%
6	9.8%
7	9.6%
8	6.7%
9	15.2%

DISADVANTAGES OF ANTICOAGULATION WITH WARFARIN

The major disadvantage of warfarin stems from the fact that its dose, safety and effectiveness can be influenced by various pharmacogenetics such as the cytochrome P450 2C9 gene, the vitamin K epoxide reductase complex 1 gene, various vitamin K containing foods (kale, broccoli, onion, spinach, lettuce, parsley), alcohol and any other medications which can act as cytochrome P450 inducers or inhibitors. Warfarin can therefore lead to an unpredictable dose response, necessitating close monitoring both on initiation and during maintenance therapy. Furthermore, when the INR is outside the therapeutic range there is increased risk of both ischemic strokes (when INR <2.0) and hemorrhagic strokes (when INR >3.5). The INR therefore has to be monitored frequently, as even in patients with stable dosing a change in diet for example can lead to either sub-therapeutic or supra-therapeutic levels. It is therefore recommended that for stable patients INR should be monitored every 4-12 weeks to confirm therapeutic range [15, 21, 22].

Nevertheless, the regular and often unpredictable need for blood testing required with warfarin can make it inconvenient; discouraging some patients from agreeing to take it either due to personal preference (e.g., needle phobia, inability to commit to regular blood tests) or geographical complications (e.g., living in rural areas with no ability to visit a facility for blood taking on a regular basis).

THE IDEAL WARFARIN REPLACEMENT

Any new oral anticoagulant should be as safe and efficacious as warfarin but at the same time more convenient and cost-effective. Despite the disadvantages of warfarin these are at least known and include slow onset of action, unpredictable pharmacokinetics and many drug interactions requiring close monitoring. Warfarin does however have many advantages, hence its use for almost a century after its anticoagulant properties were first described in 1922 [23]. All the side-effects are known, it is efficacious (especially when in therapeutic range),

inexpensive and with a once daily dosing regime, allows for good adherence. Furthermore, in cases of bleeding there are many therapeutic options to minimize harm, ranging from vitamin K replacement (for minor bleeding requiring non-urgent reversal), to potent antidotes such as fresh frozen plasma and prothrombin complex concentrates when urgent reversal is required (for example bleeding in critical areas [e.g., intracranial] or major bleeding [e.g., polytrauma]). Finally, an unintentional benefit of warfarin is that the frequent INR monitoring allows the physician to ascertain adherence. This can be very beneficial, before scheduled electrical cardioversion for example, where serial INR measurements within therapeutic range can confirm adherence and minimize the risk of stroke during the cardioversion. A new anticoagulant should therefore ideally be better than warfarin– it must have a reversal agent and a mechanism for allowing physicians to ascertain adherence and there should not be any new disadvantages. It must also be at a price considered acceptable in the new era of cost-effective pharmacotherapy.

NOVEL ORAL ANTICOAGULANTS

There are currently three NOACs approved by the Food and Drug Administration (FDA) and the European Medicines Agency (EMA) for the reduction of stroke and systemic embolism in patients with AF: dabigatran etexilate, rivaroxaban and apixaban. The discussion in this chapter will be limited to these three approved agents, although others undergoing development and testing might enter clinical practice in the not too distant future.

Dabigatran Etexilate

Dabigatran etexilate is an oral prodrug rapidly converted by a serum esterase into dabigatran, a potent, direct, competitive inhibitor of thrombin. It has an absolute bioavailability of 6.5%, with 80% of the given dose excreted renally. Its serum half-life is 12 to 17 hours, therefore requiring twice daily administration, but it does not require regular monitoring (Table 3). It was the first NOAC to complete a phase III trial, the Randomized Evaluation of Long-Term Anticoagulation Therapy (RE-LY) trial in patients with AF [24] and the first NOAC approved by both the FDA and EMA. In the trial, 18,113 patients met the criteria with non-valvular AF and at least one risk factor for stroke and systemic embolism from:

- previous stroke or TIA
- left ventricular ejection fraction $\leq 40\%$
- New York Heart Association class II or higher heart-failure symptoms within six months before screening, and aged at least 75 years or
- aged between 65 and 74 years with diabetes mellitus, hypertension, or coronary artery disease.

The study participants were randomized equally to receive either dose-adjusted warfarin (INR 2.0–3.0), dabigatran 110mg twice daily or dabigatran 150mg twice daily. This was a

non-inferiority study in which patients with renal failure and a creatinine clearance of $<30\text{ml/min}$ were excluded in view of concerns about the accumulation of dabigatran and increased bleeding risk [25]. The primary outcome was stroke or systemic embolism, occurring in 199 patients on warfarin (1.69% per annum), 182 patients on the 110mg twice daily dose of dabigatran (1.53% per annum, relative risk reduction of 9%, compared to warfarin, relative risk ratio 0.91, 95% CI =0.74-1.11; $p<0.001$ for inferiority) and 134 patients on the 150mg twice daily dabigatran dose (1.11% per annum, relative risk reduction 33% compared to warfarin, relative risk ratio 0.67, 95% CI =0.53-0.82; $p<0.001$ for superiority). Both dabigatran doses therefore proved non-inferior to warfarin with regards to stroke and systemic embolism. Rates of life-threatening bleeding, intracranial bleeding, and major or minor bleeding were significantly higher with warfarin (1.80%, 0.74%, and 18.15%, respectively) than with either the 110mg dose of dabigatran (1.22%, 0.23%, and 14.62%) or the 150mg dose of dabigatran (1.45%, 0.30%, and 16.42%). However, there was a significantly higher rate of major gastrointestinal bleeding with dabigatran 150mg compared with warfarin, which was not seen with the 110mg dose. One important association noted was that myocardial infarctions (MI) were less frequent with warfarin, at 0.53% per annum compared to 0.72% in the 110mg dabigatran dose and 0.74% in the 150mg dabigatran dose. The difference between warfarin and the higher dose dabigatran was significant ($p=0.048$). This was attributed to the beneficial effect of warfarin in reducing MI which dabigatran did not have. Finally, and importantly, there was no significant difference in overall mortality between warfarin and either dose of dabigatran (warfarin annual mortality =4.13%, dabigatran 110mg =3.75% and dabigatran 150mg =3.64%).

However, after the initial publication of the RE-LY trial results, the authors published more data that became available subsequently [26]. When the electrocardiograms of patients were retrospectively reviewed they found that 28 patients had suffered a silent MI. No such occurrences had been reported during the trial. The authors claimed that with this added data there was no longer a significant difference in rates of MI in the warfarin group and the dabigatran 150mg group. This finding should be interpreted with caution however, given the retrospective nature of data collection. A recent meta-analysis [27] has also shown dabigatran to actually increase the relative risk of MI by 33% compared to warfarin, enoxaparin or placebo for long-term use (relative risk =1.33; 95% CI, 1.03-1.72; $p=0.03$) although overall this only contributed only to a small absolute risk increase of 0.27% annually.

Analysing all the results of the RE-LY trial would suggest that the lower dose of 110mg dabigatran twice daily was associated with a similar number of total strokes as warfarin but with reduced bleeding, while the higher dose was associated with fewer strokes but a similar bleeding tendency. On the basis of this data the FDA only approved the 150mg twice daily dose dabigatran for use in the US as a novel agent conferring some reduction in stroke when compared to warfarin, whereas both doses have been approved by the EMA.

There are still some concerns about the use of dabigatran, particularly considering that despite the lower number of strokes for the 150mg dose and less bleeding for the 110mg dose, there was no significant difference in mortality. It is possible that the lack of reversing agent for dabigatran in an emergency is a factor. Haper and colleagues [28] reviewed patients who had bleeding while taking dabigatran and concluded that among other risk factors including advanced age, reduced renal function and low body weight, the lack of a reversing agent was a contributory factor to increased mortality. The reduction in stroke risk with the 150mg dose and bleeding with the 110mg dose should therefore be balanced against the inability of

managing an emergency optimally with a reversal agent. An argument could be made in favor of dabigatran, particularly the 150mg dose twice daily, that as it causes less hemorrhagic stroke than warfarin then perhaps avoidance of intracranial bleeding is more important than managing such bleeding optimally. However, both the advantages and disadvantages of dabigatran should be explained to the patients in order to enable them to make an informed decision for the treatment.

Rivaroxaban

Rivaroxaban was the first oral direct Factor Xa inhibitor to complete a phase III trial of stroke prevention in patients with non-valvular AF (the ROCKET-AF trial) [29] and the first agent from this class approved by the FDA and EMA for this indication. In this trial 14,264 patients at moderate to high risk of venous thromboembolism (CHADS score ≥ 2) were randomized using a double-blind, double-dummy approach with rivaroxaban 20 mg once daily or warfarin (with the dose regularly adjusted to maintain an INR of 2.0-3.0). Patients with decreased renal function (creatinine clearance 30-49 ml/min) received a reduced dose of 15mg rivaroxaban once daily. Patients with worse renal function were not included in the trial. Rivaroxaban has a very good oral bioavailability of over 80%, a rapid onset of action and it is 65% renally excreted with 35% excreted unchanged [30], again raising some concerns about toxicity in patients with significant renal impairment. The primary endpoint was again stroke and systemic embolism. Using an intention to treat analysis, 269 patients on rivaroxaban (2.1% per annum) and 306 patients on warfarin (2.4% per annum) fulfilled the primary endpoint giving a relative risk reduction of 12% for patients taking rivaroxaban compared with warfarin, a relative risk ratio of 0.88, 95% CI= 0.74-1.03, $p=0.001$ for non-inferiority and $p=0.12$ for superiority. Rivaroxaban and warfarin were very similar in terms of major bleeding, with 3.6% and 3.4% per annum, respectively. However, intracranial hemorrhage was less commonly observed with rivaroxaban (0.5% per annum) than with warfarin (0.7% per annum) and the relative risk reduction was 33% compared to warfarin (relative risk ratio 0.67, 95% CI =0.47-0.93; $p=0.02$). This was partly counterbalanced by an increase in major bleeding from the gastrointestinal site witnessed in the rivaroxaban group (224 events [3.2%] in the rivaroxaban arm compared with 152 events [2.2%] in the warfarin arm, $p<0.001$). Furthermore, this trial failed to prove a significant mortality benefit for the NOAC as there were 582 deaths in the rivaroxaban and 632 death in the warfarin group (4.5% and 4.9% per annum, respectively; relative risk ratio= 0.92; 95% CI =0.82 to 1.03; $p=0.15$) (Table 4), once again raising concerns about the lack of a reversing agent in an emergency.

This study was heavily criticised however because the mean percentage time that the patients taking warfarin had within the therapeutic range of INR was only 55% [31]. Although the authors claimed that 55% was an acceptable rate, many clinicians would consider this a relatively low percentage, particularly for patients enrolled in a trial, given that real-world experience both from North America [32,33] and Europe [34] shows that it is possible to maintain a therapeutic INR around 70% of the time. It has been argued therefore that this trial only succeeded in comparing rivaroxaban with poorly controlled warfarin.

Apixaban

Apixaban was the second direct oral factor Xa inhibitor to complete a direct head to head phase III trial with warfarin for stroke prevention in patients with AF (the apixaban versus warfarin in patients with AF [ARISTOTLE]) trial [35] and subsequently approved by both the FDA and EMA. Apixaban has rapid absorption, a shorter half-life of 12 hours and is 25% renally excreted (Table 3). Twice daily administration is therefore necessary but the added benefit of this is that in case of bleeding less time will be required for its anticoagulant effects to wear off. A total of 18,201 patients with AF and at least one of the following risk factors for thromboembolism were included:

- aged at least 75 years
- previous stroke, TIA, or systemic embolism
- symptomatic heart failure within the previous three months or a left ventricular ejection fraction of $\leq 40\%$
- diabetes mellitus or
- hypertension requiring pharmacologic treatment

With the use of a double-blind, double-dummy design, patients were randomized to either dose-adjusted warfarin, aiming for INR 2.0–3.0 or apixaban 5mg twice daily (or 2.5 mg twice daily in those who met two or more of the following criteria: age >80 years, body weight $<60\text{kg}$ or mild renal failure with creatinine $>1.5\text{mg/dL}$ (133mmol/L) (patients with significant renal failure and creatinine clearance $<25\text{ml/min}$ were excluded). The primary objective of this trial was to determine whether apixaban was non-inferior to warfarin in reducing the rate of stroke (ischemic or hemorrhagic) or systemic embolism among patients with AF and at least one other risk factor for stroke. The primary safety outcome was major bleeding. The primary endpoint of stroke or systemic embolism occurred in 212 patients in the apixaban group (1.27% per annum) and 265 patients in the warfarin group (1.60% per annum), a relative risk reduction of 21% compared to warfarin, relative risk ratio = 0.79, 95% CI = 0.66–0.95, $p < 0.001$ for non-inferiority and $p = 0.01$ for superiority. Both the rate of hemorrhagic and ischemic/undefined strokes were lower in the apixaban group (relative risk reduction by 49% in the former and 8% in the latter). Fatal or disabling stroke was more common in the warfarin group with 117 patients (0.71% per annum) being affected compared to 84 in the apixaban group (0.50% per annum), conferring a relative risk reduction of 29% when compared with warfarin. The ARISTOTLE trial is, to date, the only one that showed decreased mortality with a NOAC compared to warfarin (death from any cause was 3.52% in the apixaban group compared to 3.94% in the warfarin group, [relative risk reduction 11% compared to warfarin, relative risk ratio = 0.89, 95% CI = 0.80–0.99, $p = 0.047$]). However, for cardiac causes specifically (including death from hemorrhagic stroke), there was no significant difference (death was 1.80% per year in the apixaban group and 2.02% per year in the warfarin group [relative risk ratio = 0.89; 95% CI = 0.76–1.04]). Similarly, death from non-cardiovascular causes (including fatal bleeding other than hemorrhagic stroke) was 1.14% per year in the apixaban group and 1.22% per annum in the warfarin group (relative risk ratio = 0.93; 95% CI = 0.77–1.13) and the rate of MI, although lower in the apixaban group, did not reach statistical significance. Major bleeding however occurred in 327 patients in the

apixaban group (2.13% per annum), compared with 462 patients in the warfarin group (3.09% per year [relative risk reduction 31% compared with warfarin, relative risk ratio= 0.69; 95% CI =0.60-0.80; $p<0.001$]). The rate of intracranial hemorrhage was 0.33% per annum in the apixaban group and 0.80% per annum in the warfarin group (relative risk reduction 58% compared to warfarin, relative risk ratio= 0.42; 95% CI =0.30-0.58; $p < 0.001$) (Table 4). Although apixaban possibly showed the most promising results out of all the NOAC some concerns have also been raised regarding this trial; in particular, the time spent in therapeutic range when taking warfarin was perhaps lower than what can be achieved in other centers [36], again raising the concern that apixaban might simply be better when compared to poorly controlled warfarin.

When Warfarin is not an Option

Apixaban is the only novel agent to date that has been studied in patients who were unsuitable for warfarin therapy. In the apixaban in patients with Atrial Fibrillation (AVERROES) study [37], it was compared to the use of aspirin for stroke prophylaxis. Unsurprisingly, apixaban performed better in terms of reduced stroke rate with comparable mortality and major bleeding outcomes. There were 51 stroke or systemic embolism events (1.6% per annum) among patients taking apixaban and 113 (3.7% per annum) among those taking aspirin (a relative risk reduction of 55% compared to aspirin, with a relative risk reduction =0.45; 95%, CI = 0.32-0.62; $p<0.001$). Death rates were 3.5% per annum in the apixaban group and 4.4% per annum in the aspirin group (relative risk reduction 21% compared with aspirin, relative risk reduction =0.79; 95% CI =0.62-1.02; $p=0.07$). All data taken together suggest that apixaban is safer than aspirin for stroke prophylaxis in patients who cannot tolerate (or refuse) warfarin therapy.

Apixaban Use in Patients with a High Risk of Thromboembolism and Bleeding

Apixaban has also been to date the only NOAC comparing anticoagulation against warfarin for patients in AF categorized according to two thromboembolic risk scores (CHADS₂ and CHA₂DS₂VASc) and one bleeding score (HAS-BLED) [38]. In a sub-analysis of patient risk in the ARISTOTLE trial there was no statistical heterogeneity of response across the different risk categories. A possible explanation for this was that apixaban could benefit every patient equally, regardless of their thromboembolic and bleeding risk. Alternatively, as commented in an accompanying editorial, being a subanalysis of the ARISTOTLE trial, this was not sufficiently powered to confirm such a difference and advised therefore for the results to be interpreted with caution [39]. In addition, careful analysis also suggested that the numbers needed to treat (NNT) to prevent one stroke varied significantly from approximately 120 for those with CHADS₂ =1 and about 60 for those with CHADS₂ ≥ 3 , indicating that patients with a higher thromboembolic risk might benefit more from a NOAC and this could significantly affect cost-effectiveness.

Table 3. Showing the relative pharmacokinetics of the novel oral anticoagulants

	Dabigatran	Rivaroxaban	Apixaban
Target	Thrombin	Factor Xa	Factor Xa
Dose	Twice daily	Once daily	Twice daily
Half-life in hours	12-17	5-9 (but effect lasting for 24 hours)	12
Renal excretion	80%	25%	33%
Hepatic excretion	20%	75%	67%

ORAL ANTICOAGULATION AND BLEEDING RISK, CAN WE PREDICT THE INDIVIDUALS WHO WILL BLEED?

Unfortunately there are common risk factors for bleeding and thromboembolism. Hypertension, previous stroke and older age put patients both at risk of bleeding and thromboembolism and therefore the relative benefit of anticoagulation should be assessed against predicted bleeding risk for every individual. There are currently three bleeding scoring systems for use in patients with AF: HEMMORR(2)HAGES, ATRIA and HAS-BLED. The HAS-BLED is an easy scoring system to use; in a recent comparison it outperformed the other two, although the ability to predict bleeding was only modest [19]. In order to calculate a HAS-BLED score, a single point is added for hypertension, renal disease, liver disease, previous stroke, labile INR, age ≥ 65 , other medication predisposing to bleeding (e.g., aspirin or other non-steroidal anti-inflammatory drugs [NSAIDS]) and alcohol intake. A score of ≥ 3 represents a significant risk of bleeding. At present the most important reason for estimating the bleeding risk is not to prevent initiation of anticoagulation but to identify patients who might benefit from risk factor modification e.g., stopping aspirin if not required, introducing anti-hypertensive medication and support to reduce alcohol intake in order to minimise bleeding risk [40].

A recent analysis from Denmark assessed patients in AF on warfarin with both the CHADS₂ and CHA₂DS₂-VASc scoring systems and the risk of bleeding using the HAS-BLED system. The findings support the view that anticoagulation should be offered even in patients at the highest risk of bleeding (HAS-BLED ≥ 3), as paradoxically this is the group of patients who benefit the most (probably because they also have a significant thromboembolic risk) [41]. The same appears to be true for apixaban use in patients with AF [38] where the incidence of major bleeding was 3.46% for patients with HAS-BLED ≥ 3 and 2.25% for HAS-BLED=2 while intracranial bleeding was 0.23% and 0.38% respectively.

Based on the currently available evidence the decision to anticoagulate an individual patient with AF remains a nuanced one, balancing the Scylla of thromboembolism against the Charybdis of hemorrhage, both risks imperfectly predicted by even the best risk stratification scores. However, even if there is a high bleeding risk, following appropriate discussion with the patient, suitable candidates should be offered anticoagulation. Novel oral anticoagulants, particularly apixaban, might prove very cost-effective in this high risk subgroup of patients.

Table 4. Showing the outcomes of the trials of the three novel anticoagulants versus warfarin

	Stroke or systemic embolism/ annum	Major bleeding/ annum	Myocardial infarction/ annum	Intracranial bleeding/ annum	Hemorrhagic stroke/ annum	Mortality/ annum	INR within therapeutic range
RE-LY							64%
Dabigatran 110mg	1.53%	2.71% *	0.72%	0.23% *	0.12% *	3.75%	
Dabigatran 150mg	1.11% *	3.11%	0.74% *	0.30% *	0.10% *	3.64%	
Warfarin	1.69%	3.36%	0.53%	0.74%	0.38%	4.13%	
ROCKET-AF							55%
Rivaroxaban	2.1% *	3.6%	0.9%	0.5% *	0.3% *	4.5%	
Warfarin	2.4%	3.4%	1.1%	0.7%	0.4%	4.9%	
ARISTOTLE							62%
Apixaban	1.27% *	2.13% *	0.53%	0.33% *	0.24% *	3.52% *	
Warfarin	1.60%	3.09%	0.61%	0.80%	0.47%	3.94%	

The * indicates a statistically significant difference between the novel oral anticoagulant and warfarin.

CONCERNS ABOUT THE USE OF NOVEL ORAL ANTICOAGULANTS

The results of the trials comparing the three NOACs with warfarin for stroke prophylaxis in AF highlight several important limitations. Patients on warfarin did not achieve a good time in therapeutic range. In the dabigatran trial patients on warfarin had a mean time in therapeutic INR range of 64%; in the rivaroxaban trial the patients had a mean time of 55% and in the apixaban trial the mean time was 62%. We therefore cannot extrapolate the results to patients who have remained stable on warfarin and in therapeutic INR range for more than 70-75% of the time, which is more representative of real-life practice in North America and Europe [32-34]. Furthermore, these anticoagulants are relatively new. Rare but possibly significant side-effects might not have become fully apparent yet. Some concerns have already been raised regarding the lack of specific reversing agents for them, their use in moderate renal failure, underweight or overweight patients or even in elderly patients [28, 42]. There is also the risk of both undercoagulation and supracoagulation during the period of switching a patient from warfarin to one of the NOACs [28]. Formal guidance is awaited in order for this process to be completed safely. In addition, there is a need for vigilance and the collection of appropriate information on possible side-effects in order to ensure that the profile of NOACs remains a safe one. This is especially important considering the case of the “novel” anticoagulant, ximelatragan, where increased episodes of lethal hepatotoxicity were not fully appreciated until phase IV trials, promptly leading to its immediate withdrawal. Finally, in an era of financial concerns, new medication will have to prove their cost-effectiveness in addition to their safety and improved efficacy [43].

SO WHAT SHALL I DO DOCTOR?

Many patients nowadays are very well informed about their medical conditions and it is likely that based on online resources they will be aware of the possibility of taking a NOAC instead of warfarin for AF. Undoubtedly for some patients a NOAC might be more appropriate but the important question remains however whether a NOAC is more appropriate for every patient? The answer is probably not, at least not yet as demonstrated in the following scenarios with recommendations based on currently available evidence:

Case 1

A 78-year-old man with hypertension, diabetes and AF has been on warfarin for four years. He is stable with an INR in therapeutic range >80% of the time. He requires blood monitoring every 4-6 weeks and is happy with the necessary dietary restrictions. He is seen in clinic and enquires whether he should be taking a NOAC.

This is a common scenario, seen in most cardiology outpatient clinics. None of the main trials were powered to compare a NOAC with good warfarin control and we therefore do not have the evidence to suggest that switching to a NOAC for this particular patient will reduce either his risk of bleeding or thromboembolism, so the advice should be to continue with warfarin. Had his time in therapeutic range been <60% instead, then a NOAC could have been offered.

Case 2

A 45-year-old man with no risk factors for thromboembolism is scheduled to undergo electrical cardioversion.

One of the benefits of warfarin use is that it enables physicians to ascertain adherence. In this scenario confirming adherence and therapeutic INR in the weeks leading up to the cardioversion is crucial as it minimizes the risk of thrombus formation and the possibility of stroke following the cardioversion. Patients anticoagulated with warfarin often present for elective electrical cardioversion but are found to have sub-therapeutic INRs. It is only at this point that they admit/ remember that they have missed a warfarin dose. NOACs will not allow such an opportunity for monitoring, potentially leading to electrical cardioversion of patients who have not been adequately anticoagulated. Such patients should be managed with warfarin until a few weeks after the cardioversion and the need for anticoagulation addressed subsequently, where a NOAC might then be appropriate.

Case 3

An 88-year-old woman with AF, partially sighted with previous TIA, hypertension and peripheral vascular disease who lives alone in an area with no easy access to a clinic or community practitioner to monitor INR. Her time in therapeutic range for the last year was 40%. Two months ago she had significant bruises and her INR was found to be 6.4 and since then she has refused to take warfarin.

A patient who spends significant time outside therapeutic range is at risk both of significant bleeding when the INR is high and ischemic stroke when the INR is low. This woman has a $CHA_2DS_2-VASc = 7$ and an estimated annual risk of thromboembolism of about 10%. She will therefore benefit greatly from anticoagulation. Given the difficulties in maintaining warfarin within therapeutic range and the geographical difficulties associated with regular blood testing, it would appear that the risks of warfarin outweigh the potential benefits. Some patients, especially younger ones, might be able to self-monitor INR and warfarin dose at home; this appears to reduce some of the side-effects associated with warfarin [44]. However, antiplatelet therapy either with aspirin monotherapy or dual therapy with aspirin and clopidogrel will only reduce this patient's thromboembolic risk moderately and should not be recommended as a warfarin substitute. Therefore, in keeping with the findings of the AVERROES trial [37], apixaban 2.5mg twice daily would be the most appropriate NOAC to use.

Case 4

A 73-year-old woman with permanent AF for six years and a coronary stent in the LAD, inserted 15 months ago. She also has hypertension and gastroesophageal reflux. She

tolerated warfarin, aspirin and clopidogrel for 12 months and currently, following the advice from the interventional cardiologist, takes aspirin and warfarin. Her time in therapeutic INR is 60-70%.

With an aging population facing both coronary disease and AF, this scenario will become more common. A NOAC will not offer any protection from stent thrombosis and therefore this woman needs to continue with aspirin. The use of a NOAC plus aspirin might prove superior to warfarin plus aspirin but this has not been assessed in a trial. There have been some concerns about dabigatran and an increased risk of MI [27]. In this case, on the basis of current evidence, it might be appropriate to continue with aspirin and warfarin and in the future the patient might even be allowed to continue on warfarin monotherapy [45]. If however she refuses warfarin, it would be acceptable to consider a combination of aspirin and apixaban or aspirin and rivaroxaban although there is no direct evidence to support this at present.

Case 5

A 67-year-old man with hypertension, diabetes and asymptomatic permanent AF. He refuses to consider warfarin and has been on aspirin monotherapy for seven years.

The results of the AVERROES study [37] indicate that this patient (who refused to consider anticoagulation) will have prognostic benefit if he takes apixaban 5mg twice daily. Although not directly compared with aspirin, the other two NOACs, dabigatran in the RE-LY trial [24] and rivaroxaban in the ROCKET-AF trial [29], are also likely to benefit this patient as they compared favorably with warfarin in those studies. The most cost-effective NOAC should therefore be considered for this patient. If however, cost-effectiveness is similar across the three options, then apixaban is the one that has the most evidence to support its use in this case.

It is important to highlight that NOACs can only be used in patients with isolated non-valvular AF. They are not appropriate for patients with AF and an additional pathology e.g., a metallic heart valve. However, although a NOAC should not be offered routinely as a first-line treatment for anticoagulation in isolated AF, they can provide an excellent alternative to warfarin, particularly for patients with a low percentage time in therapeutic range (e.g., case 3 above). Physicians should therefore monitor time spent in therapeutic range during their clinic appointments as we now have the option of switching to something that is likely to be more effective than warfarin for such patients.

CONCLUSION

The NOACs offer a variety of therapeutic options for patients in AF who require thromboembolic prophylaxis and are likely to shape the future of anticoagulation. However, on the basis of the evidence available to-date, considering on the one hand the benefits, risks and convenience they offer and on the other, their cost-effectiveness in “real life” clinical practice [43], one cannot recommend any of the NOACs as panacea and first-line therapy for

every patient. Some patients, particularly those with high thromboembolic and bleeding risk, with poor INR control or refusing warfarin are probably the ones to benefit most from a NOAC. Over the next few years a NOAC should therefore be offered initially to these high-risk patient groups. Warfarin will probably remain in use for the majority of patients with AF for the next few years and is likely to celebrate its centurial birthday. However, with improved NOACs on the horizon, over the next decade warfarin is likely to lose its place as the most commonly used anticoagulant for AF.

Chapter 61

STROKE IN ELDERLY

Mehmet Kolukısa and Talip Asil

Bezmialem Vakıf University, Faculty of Medicine, Department of Neurology
Istanbul/Turkey

ABSTRACT

Cerebrovascular diseases are one of the leading causes of mortality and disability, and they necessitate long-term care. Vascular dementia, on the other hand, is the second most frequent cause of dementia in the geriatric population.

The nihilistic approaches to stroke have been changed as a result of increasing availability of stroke units with trained staff and the recent improvements in acute stroke treatment.

However, the shorter treatment intervals decrease the amount of patients who can benefit from treatment.

In addition to patient based and treatment-focused approaches, the determination of preventable strokes via population based and preventative approaches will reduce the social and economical burden.

STROKE IS A GERIATRIC DISEASE

According to the WHO definition, stroke is a sign or symptom related to focal or general cerebral function loss, which does not have any other cause except for vascular reasons. It appears suddenly and lasts more than 24 hours [1]. The definition of cerebrovascular diseases, on the other hand, not only involves conditions such as embolism, thrombosis, or vascular laceration, but also conditions related to blood vessels such as atherosclerosis, hypertensive atherosclerotic changes, arthritis, abnormal enlargement of vessels and developmental malformations, all of which occur in the brain as a result of pathological changes.

Stroke prevalence is defined as the number of new strokes and stroke incidences seen in a specific population in a specific time period, and also the total number of old and new strokes seen again in a specific population in a specific time period. Stroke incidence must be seen as the total number of hospitalized, sudden and fatal cases, which can not be hospitalized. The

American Heart Association reported that in USA 7,000,000 people, who were older than 20, managed to survive after stroke. They also reported that each year almost 610,000 patients experienced a first stroke and almost 185,000 patients experienced recurrent stroke [2]. Stroke ratios, which are arranged according to age depending on the country of the study, the demographical characteristics of the population, and the methodological approaches used in the study, display a change of 1-3 cases per 1000 patients. While this ratio was found as 1.67 for white men and 1.38 for white women, it was reported that this ratio was 3.23 for black men and 2.60 for black women in the Northern Manhattan Study [3]. These ratios are usually similar to each other in white populations on which most of the reliable stroke incidence studies are done. On average, 2 new stroke incidences show up in every 1000 people. The proportion of people living in those populations, who had a previous stroke, is around 6 per 1000.

Since the 1950s, there is a decrease in stroke frequency. In the study of Rochester, Minnesota, it was stated that there was a 46% decrease in cerebral infarct and hemorrhage frequency between the years 1950-1952 and the years 1975-1979 [4]. Another study indicated that stroke frequency decreased 20% from 1968 to 1976 [5]. Contrarily, stroke incidence was found to be 17% higher in the years 1980-1984 compared to 1975-1977, in spite of the fact that there were improvements in the treatment of hypertension. However, this result was explained by the increased usage of CT, which facilitates the determination of silent stroke incidences [6].

Totally, in most industrialized countries, 10% of death cases occur because of stroke. Japan and China are the countries in which death ratios are mostly related to stroke. Furthermore, stroke is the leading cause of adult death in Japan [7]. In the USA, approximately 130,000 mortal cases are related to stroke, and stroke is seen as the leading cause of death in adults [8]. The range of stroke mortality changes 5-10% in 1000 per year. According to 2008 data in Turkey, on the other hand, the death ratio due to cerebrovascular diseases in the age group of 40-45 was found to be 4.5%, whereas it was found to be 9.4% in people older than 75 [9]. In the USA, it was declared that the death ratio related to stroke was 34.8% and the death ratio exactly caused by stroke was 19.4% between the years of 1998-2008 [10]. The data acquired by the National Hospital Discharge Survey supported the idea that the decrease in stroke mortality can be explained by the increase in survival ratios after stroke rather than the decrease of stroke mortality. Recent statistics, however, indicated that the decrease in stroke mortality reached its maximum level and the total number of strokes can start to increase again. According to the projections made by the AHA for 2030, stroke prevalence will increase 24.9% compared to 2010 and there will be 4 million more patients suffering from stroke in the USA [11].

To conclude, 30% of patients with stroke die in one year, up to 20% of them die in the very early phases. Additionally, 1/3 of patients who survived after stroke continue their lives needing care from others. The need of care from others is a burden to the population in terms of both economical and social aspects.

Another reason for the increased social burden due to stroke, can be vascular dementia. In recent years, there has been an increase in the prevalence of vascular dementia due to the increased life span and also due to the proportion of increased stroke survivors.. Stroke is the second most important cause of dementia in the world. In Japan, vascular dementia comprises 50% of all dementia cases, and stroke is known as the primary cause of dementia [12]. In western countries, on the other hand, vascular dementia comprises only 4-27% of all

dementia cases, and it is the most frequent dementia type after neurodegenerative dementias [13]. The geographical changes in prevalence probably depend on the geographical distribution of stroke, especially hemorrhagic stroke, and hypertension, all of which are seen more in Asia [14].

Although the prevalence of dementia was underestimated due to the lack of criterion in previous research, the prevalence of dementia after stroke was estimated as 20-25% in studies, which involved DSM-III-R criterion for the definition of dementia [15-16].

In one of the studies, excluding the cases of experienced stroke and dementia, it was found that the ratio for newly diagnosed dementias after stroke was 14% [17]. Another study determined that patients who had stroke had a 9 times greater risk for dementia 3 months after stroke, compared to a group of equally aged patients of the same gender, and predisposed to dementia [18].

Age and arterial hypertension are one of the most important risk factors for the development of dementia following stroke [19]. In one study, the ratio of the development of dementia one year after stroke was found as 5.4% for patients older than 60 and 10.4% for patients older than 90 [20]. The ratio of development of dementia following the development of lacunar infarct was 23.1% and this ratio was 4-12 times higher compared to control groups [21]. It should be noted that even the case of stroke is not clear; the dementia process can develop in multiple but silent cerebral infarct cases. The prevalence of silent cerebral infarct is 11% in the age group 55-64, while this ratio increases up to 43% in the age group older than 85 [22].

Risk factors are defined as the reasons for creating a tendency for a disease to be developed. Age is accepted as the most important risk factor and the most powerful indicator of stroke. After the age of 55, the prevalence of stroke doubles every ten years [23].

70% of people having stroke are older than 65 [24]. Stroke develops later in women compared to men. In the USA, the average age of stroke occurrence is 75 for women, whereas it is 71 for men [25].

In conclusion, stroke is one of the most important and frequently seen diseases in the geriatric population, leading to significant mortality and disability.

PREVENTABLE STROKE

In spite of the fact that there are social awareness studies and that recanalization-reperfusion strategies are thought of as the only effective treatment for patients with acute ischemic stroke, only a few patients having stroke can benefit from this prevention because the window for this option is highly limited. Via the widely spreading stroke units, with private staff members for stroke treatment and follow-up, the ratios for stroke mortality and disability decreased. In spite of the improvements in treatment and patient care, on the other hand, 1/3 of patients die each year [26]. That's why, while there is a search for methods to increase the thrombolytic treatments for candidate patients, public health must be arranged to treat processes related to stroke and particularly, to know how to prevent strokes.

As the main cause for long-term disability, stroke results in enormous problems for patients, families of patients, and health corporations in terms of social, economical, and emotional aspects of life. The estimated whole-life cost of a patient with stroke is 140,048

USD in the US, where one person dies of stroke every 4 minutes [27]. In recent years, although the improvements, especially in acute stroke treatment, are exciting because it results in a decrease in the helplessness of stroke; the number of patients who undergo and succeed with these treatments is not enough. Therefore, it is very important to take measures for both primary and secondary stroke prevention.

It is highly important in the definition of preventable stroke to diagnose and especially consider temporary ischemic attacks; it is also essential for society to investigate and find necessary treatments for the carotid artery and atrial fibrillation in specific age groups in terms of large vein atherosclerosis and cardioembolic strokes, which are the main causes of stroke. In addition, the aim to decrease the frequency of hypertension is another important point for society because it is a shared part of the etiopathogenesis of all different stroke groups. Such measures and efforts, taken to prevent primary and secondary stroke attacks, can be the most appropriate approaches in terms of social security politics.

The most important segment of the preventable stroke group is temporary ischemic attacks. As yet unburdening but alarming signs, transient ischemic attacks should be regarded as signals, which should not be missed, for both patients and clinicians.

TIA is defined as neurological dysfunctions related to focal cerebral ischemia, generally lasting less than one hour, and without the symptoms of acute infarct [28]. TIAs can be considered similar to stroke in terms of their similar etiopathogenesis and physiopathology. The symptoms must reflect dysfunctions in a specific area in the brain. Global definitions, such as confusion or loss of consciousness and symptoms such as seizures or involuntary movements derive from TIA [29]. A discriminative TIA definition can be made related to the duration.

The infarct findings in some patients' imaging after TIA claim that the definition of TIA is untrue; and those patients can be regarded as having cerebral infarct with transient symptoms [30]. It was reported that the incidences of TIA in a population older than 75 was 2.3/1000 [31]. When patients with stroke were analyzed in terms of TIA history, 4 studies in Europe claimed that 15-26% of strokes involved TIA before stroke and 43% of them had occurred in the last week [32].

50% of the infarcts following TIAs occur within one year, including 20% in the first month after TIA [33]. In another study, it was found that the risk of stroke after TIA occurs is 10% in 90 days, with half of them in the first 2 days [34]. 25% of patients with TIA suffered from stroke or another unwanted vascular experience within 90 days [35].

31-78.6% of TIA cases involve carotid artery stenosis and occlusion, whereas 16% of them include AF [36]. It is important to diagnose TIAs, which can be an indicator of future heavy strokes that are largely preventable with appropriate treatments. As a result, professionals should create suitable definitions about the symptoms related to the carotid system such as amorozis fugax, aphasia, paresis and hypoesthesia, as well as symptoms related to vertebrobasilar system such as vertigo, ataxia, diplopia, dysphasia in order to improve public awareness. Defining this clinical presentation, which is not different from stroke in terms of etiopathogenesis, with phrases like 'stroke precursor' instead of 'transient' may be more explanatory and may better emphasize its importance.

In terms of an etiology arranged according to the most common reasons, ischemic strokes can be mainly classified as atherothrombotic strokes, cardioembolic strokes and lacunar strokes.

Similarly, different results were also stated in the frequency of the subtypes of infarct according to the geographical areas of studies, characteristics of the chosen groups, and methods. While cardioembolic strokes as a source appeared in 15-30% of all infarcts, large vein atherosclerosis appeared in 15-40% and small vein lacunar infarcts appeared in 15-30% of the cases [37]. In spite of detailed investigations, idiopathic stroke cases were stated as 40%, which is a considerably high ratio [38].

LARGE VESSEL DISEASE

Approximately, 1/3 and 1/2 of all ischemic strokes are related to large vessel atherosclerosis. This type of ischemia occurs via the thrombosis resulted from the degeneration of the stabilization of atheroma plaques, which develop in large vessels especially in the areas of bifurcation. The developed atherothrombotic lesion not only results in stenosis and occlusion in the vessel but also makes it possible for an infarct to be developed in more distal watershed areas via hemodynamic mechanisms. Furthermore, it is possible for a distal vessel to be blocked by the pieces from an atherothrombotic lesion from artery to artery with the mechanism of embolism [39].

The clinical effects of atherosclerosis can only be seen in the middle-advanced ages, although it starts very early in adolescence and even in childhood ages. The presence of hypertension, hyperlipidemia and DM, smoking, low HDL, high LDL and homocysteine levels are known to facilitate the atherosclerotic process [40]. Atheromatous lesions may regress via various medications and diet, but they can be also observed in spontaneous regression. Atheromatos lesions develop very silently for years, but the complete embolism always occurs as a result of superimposed thrombosis. Usually, if the atheromatous process is heavy, then the possibility of a thrombotic complication is also high. However, these two processes do not always develop together. While a vessel of a patient with only a few atheroma plaques can be thrombosed, a thrombosed vessel can be absent in a patient with a clear atherosclerosis. It is both possible to see a patient have a vessel with different stenosis ratios together, and another patient to have an occluded carotid but not have carotid atherosclerosis. Poor dietary habits leading to obesity, the presence of familial history and infections and inflammations accelerating the atherothrombotic process may be indicators of the case. Studies related to the atherothrombotic process can lead to new results in clinic.

In the anterior circulation, atherothrombotic lesions are usually located at the origin of the internal carotid artery and siphon part, and in the posterior circulation, they are located at the origin and at the intracranial portion of the vertebral artery, as well as in the proximal basilar artery [41]. Stroke can be developed in different pathophysiological processes in patients with atherothrombosis in extracranial or intracranial vessels. When the thrombus is settled in an advanced atheroma plaque, the lumen either becomes narrowed or totally blocked. When the vessel is blocked, a blood clot is formed related to the ceased flow, it can go forward into the distal, and finally an infarct takes place if the collateral flow is not sufficient in the distal of blocked vein. Furthermore, the immigration of thrombus or plaque fragments into the distal can create an infarct in the distal via emboli from vein to vein. Additionally, cortical and deep watershed infarcts can occur in advanced stenosis or occlusions of extracranial or intracranial vessels due to brain hypoperfusion. Those different physiopathological processes can result in

different clinical reflections. There can be cases in which stroke takes place as a lone attack in a couple of hours or cases in which the neurological disease takes root with TIAs in a couple of days.

Carotid artery disease can be seen with other atherosclerotic processes in peripheral and coronary vessels. That's why, stroke attacks in patients whose other vessels are found to be malfunctioning, or patients who are in a specific age group with a high risk of venous diseases, or with TIA, may be prevented by non-invasive scanning methods such as Doppler.

The elimination of plaque in the internal carotid artery decreases the risk of stroke in the future. As an alternative method, surgery for the removal of narrowness came into being as a result of the insufficiency of medical treatments to prevent stroke in specific patients and the failure to prevent the development of atherosclerosis.

Endarterectomy operations are one of the most common operations used for almost 50 years. The 2-year risk of stroke in patients with bilateral carotid diseases was 69%, whereas the same risk was 22% in patients who were operated on [42]. Therefore, surgery can be advised to patients with symptomatic stenosis larger than 70% in institutions with operation complications lower than 6%. This benefit is also valid for aged people, and it is actually more clear for patients who are older than 75.

ASYMPTOMATIC CAROTID ARTERY DISEASE

In a population older than 65, more than 50% of asymptomatic carotid stenosis was determined in 7-10% of men and 5-7% of women [43]. In various studies, the risk of ipsilateral stroke was found as 1-3.4% in patients with 50-99% stenosis [44]. The risk is higher especially with rapid growth of plaques. The determination of silent infarcts via imaging in cases without having clinical symptoms yet is highly important. Evaluating the risk of stroke in those patients and determining the necessity of preventive treatment can be life saving.

When the studies of ACAS and ACST were taken together, this operation can be advised for patients having 60-99% asymptomatic carotid stenosis, with a life expectancy over 5 years, in institutions with a surgical risk lower than 3% [45].

Especially after the filter usage, the area of utilization of endovascular methods to eliminate advanced carotid disease in patients who were not appropriate for endarterectomy has expanded as a result of accumulated experiences and techniques developed related to the operation. There are many studies comparing carotid endarterectomy with the endovascular method in advanced narrowness of the carotid. Most of the findings of those studies showed that the endovascular method was not as successful as endarterectomy, especially in the prevention of stroke recurrence. However, it was observed that in patients who underwent stent angioplasty, most of the strokes seen, especially in early periods, were minor strokes and did not create any clinical problems [46]. As a randomized and head-to-head comparison study of endarterectomy and stent/angioplasty applications in carotid patients, CREST showed that, on the other hand, the clinical benefit of endovascular methods was not lower than endarterectomy in patients with angioplasty/stent especially younger than 70 [47]. The application areas of endovascular methods gradually increase in stenosis of vertebral artery proximal and intracranial stenosis, which cannot be reached via surgery. In the study of

SAMPRiSS, endovascular attempts for intracranial stenosis were not routinely advised because there were too many complications. However, it was still regarded as the only option for specific patients with intracranial narrowness whose conditions could not be stabilized via medical treatments [48]. As technical facilities and clinical experiences increase in the future, more areas for clinical application can be expected in patients with intracranial stenosis.

Intracranial artery stenosis is commonly seen in the basilar artery, V4 segment of the vertebral artery, MCA M1 segment, and intracranial ICA segments. They constitute 8-10% of all ischemic stroke cases [49]. In the study of WASID, the ipsilateral stroke ratio in symptomatic intracranial narrowness was found between 13-14% in 1.8 years [50]. The ratio for ischemic stroke was 19% in more than 70% of stenosis patients in one year [51].

CARDIOEMBOLIC STROKES

It is thought that 1/4 and 1/3 of all ischemic strokes are originated from cardioembolic reasons [52]. In contrast to the prodromal large vessel atherothrombotic strokes, emboli originated strokes are discriminated by clinically sudden onsets, maximal deficit in onset period with seizures, headache, and changes in consciousness. They can occur at any hour of the day and they do not have any stimulant episodes. The sudden onset of a stroke and the absence of prodromal signs indicates embolism in patients with a history of cardiovascular disease. Approximately equal in two hemispheres, the MCA territory especially in superior division territory is involved. Although large embolic blood clots can block large vessels, such as carotid, they usually hold onto areas in which lumen become narrow. An embolic blood clot may block the lumen where it is located or more often it breaks up into smaller pieces that lodge to smaller distal vessels. In this case, clinical effects can recover in a couple of hours. In the case of a sudden settlement of embolic blockage, on the other hand, collateral flow cannot develop and clinical tables settle down permanently. Embolic blockage of cerebral and cerebellar superficial branches can give rise to specific syndromes such as focal motor deficit, isolated aphasia or hemianopia. In 2 weeks after the first embolic event, an arterial or cardiac originated recurrent embolic event takes place with a 10-20% ratio [53]. Therefore, the emboli source should be determined in early stages.

The most common cause of embolic infarct is determined as chronic or new atrial fibrillation (AF). Nonvalvular AF is accepted as being responsible for 45% of cardioembolic strokes [54]. According to the Framingham Heart Study, patients with chronic atrial fibrillation experience 6 times more strokes compared to a population in the same age group with a normal heart rhythm. While the risk of stroke in the presence of AF is 1% in patients younger than 65, this ratio can increase to 8% in patients older than 75 with additional risk factors [55]. Literature shows that the first stroke in the presence of AF progressed 2 times more fatally compared to the cases without AF, and the risk of recurrent stroke in people who survived was higher [56].

AF is the most common rhythm dysfunction in patients with arrhythmia in USA [57]. The mean age of patients with AF is around 75, and 70% of them are in the 65-88 age group. 84% of the patients are older than 65 [58]. In two different studies with 5-15 years of observations, it was found that the prevalence of AF was between 5 and 9% in a population older than 60 [59].

The presence of incidental AF is a significant condition that deserves attention. 12% of patients who participated in Cardiovascular Health Study and 45% of patients in the SPAF 3 study were found to have incidental AF by coincidentally having EKGs for different reasons. [60-61]

The ratio of symptomatic AF to asymptomatic AF was found to be 12/1 [62]. The increased ratio of stroke in aged patients is not only dependent on the age-related increase in the ratio of AF; when the aged patients and young patients with AF were compared in terms of the risk of having a stroke, it was found that aged patients with AF had a higher risk for stroke. The presence of old age, volumetric increase in the left atrium and chronic rhythm dysfunction increase the risk in patients with AF. The atrial fibrillation itself is also thought to be a factor leading to a hypercoagulated condition. It was found that there was no difference between paroxysmal AF and chronic or permanent AF in terms of being a cause of stroke [63].

Most of the studies confirmed that warfarin is efficient for preventing stroke in patients with non-valvular atrial fibrillation. Those studies found that control groups had a 4.5% annual rate of stroke, while people who used anticoagulants had a 1.4% annual rate of stroke [64]. According to the common result acquired by primary prevention studies, oral anticoagulant treatments prevent stroke in 31 patients per 1000, and ASA prevents stroke in 15-20 patients per 1000 per year [65]. The efficiency of prophylactic anticoagulation is especially clear in patients older than 75 and having additional risk factors [66]. As a result, if the rhythm of patients with newly diagnosed AF cannot be ameliorated by cardio-version and antiarrhythmic medications, a prophylactic anticoagulant is advised. In the study of EAFT related to secondary prevention, it was determined that anticoagulant treatment was a quite effective treatment to reduce embolic complications in patients newly suffering from an ischemic attack. Also, ASA can be used in cases in which anticoagulant treatment was contraindicated and less efficient [67]. The ACTIVE-A study, on the other hand, showed that double antiaggregant usage was more effective in patients with AF compared to single aspirin usage, but it also produced an increase in hemorrhage complications [68]. 1/3 of adults with atrial fibrillation were people younger than 65 without additional risk factors, and it was found that this group, having a low risk of stroke, did not benefit from long-term prophylactic anticoagulation. Therefore, it is important for patients with AF to evaluate the risk of vascular incidents and the possible complications of using oral anticoagulants. For this reason, clinical scoring methods were developed and clinical reliabilities of those scores were controlled. CHADS2 and CHADS2Vasc scores are used in patients with AF in order to determine the vascular risk. While aspirin is preferred as prevention for patients with a low score, oral anticoagulant usage is advised for patients with moderate to high vascular risk. It is also possible to predict the annual hemorrhage ratios related to the use of oral anticoagulants via another clinical score called HAS BLED [69]. There are studies using not only clinical but also imaging methods to predict hemorrhage ratios. For instance, it is known that the determination of microhemorrhages in Gradient- Echo T2-weighted MR sequences increased the frequency of oral anticoagulants-dependent intracerebral hemorrhage [70].

The alternatives of warfarin were investigated for patients with AF because of its usage difficulties. It was found that ximelagatran, a direct inhibitor of thrombin, was as effective as warfarin in patients with AF in preventing ischemic stroke, and its hemorrhage complications were found to be less than warfarin [71]. Because it resulted in an increase in hepatic enzymes, on the other hand, ximelagatran could not be recommended for routine use. The

study of RELY performed in patients with AF, but without valvular heart disease, demonstrated that as a direct thrombin inhibitor, dabigatran was found to be as effective as warfarin in preventing vascular events and stroke, and to be slightly better in terms of hemorrhage complications [72]. Similarly, studies showed that apixaban and rivaroxaban, as direct thrombin inhibitors, can be used orally. They are an alternative to warfarin.

LACUNER STROKES

Lacunar strokes constitute the third group following large vessel atherosclerosis and cardioembolic strokes. While it was previously regarded to be in the same category with other ischemic strokes, its importance has become clearer in recent years. The clinical syndromes peculiar to this group of patients are easily recognized by clinicians and create positive expectancies about the prognosis. Major clinical syndromes are motor hemiparesis, pure sensory hemiparesis, dysarthria, clumsy hand, ataxic hemiparesis, and sensory motor syndrome [73]. It usually starts suddenly and recovery, sometimes almost the entire recovery, can take place in a couple of hours, days or weeks, even though the stroke was serious in the beginning.

Lacunar infarcts occur as a result of the occlusions of small penetrant terminal branches which do not have collaterals of large cerebral arteries [74]. Various mechanisms are proposed about the formation of lacunar infarcts. The increased arterial pressure produces gradual damage in the wall of the small penetrant artery, and vessel lumen becomes blocked via fibrosis connective tissue or fibrinoid material. It can end with lipohyalinosis pseudoaneurysm. Atheromatosis blocking the penetrant artery can create a lesion microatheroma. Atherosclerotic plaque in the large vessels can impair perfusion by blocking the penetrant artery orifice, or bringing about lacunar infarcts in embolies originated by the heart and large vessels [75].

Hypertension is the main component in etiopathology in terms of lacunar strokes. In almost every clinical and pathological investigation, a strong correlation was found between the lacunar state and chronic HT, and also a less strong but significant correlation between DM and HL. In the study of Rochester, Minnesota, hypertension was found in 81% of patients with lacunar infarct [76].

Population-based imaging studies show silent infarct as high as 28%, however lacunar infarcts were associated with a relatively good prognosis [77]. A potential cardioembolic source could be determined in approximately 8% (0-17%) of patients with lacunar infarct and more than 50% of stenosis and occlusion on the ipsilateral carotid artery in approximately 15% (3-63%) [78]. Another study showing 92% of determined lacunas are silent stated that those patients had unnoticed neurological deficits [79].

Small vessel dementia is called subcortical ischemic vascular dementia and it is regarded as the most common cause of dementia comprising almost half of the cases [80]. Both cortical and subcortical areas are influenced in lacunar events, while lesions are limited to subcortical areas in Biswanger disease. The ratio of the development of dementia 4 years after lacunar infarct was 23.1% and this ratio was 4-12 times higher than controls [21]. Dementia in lacunar infarcts is seen in 11% of patients at the end of the 3rd year, whereas this ratio increases up to 23% at the end of the 9th year [81]. The development of different kinds of

diagnosis criterion and the term ‘vascular cognitive impairment’ is used instead of ‘vascular dementia’ in order to show the causal relationship between the vascular process and cognitive impairment. This can be helpful in diagnosing the cases earlier and therefore include preventions for vascular dementia including subcortical damage and executive dysfunctions rather than memory impairments, especially in early phases. This is contrary to traditional dementia, which includes the development of deterioration in daily life activities and prioritized memory impairments.

Lacunar strokes should not be taken lightly, as innocent cases ending up with harmless results, because the accompanying diseases and especially recurrent lesions lead to cognitive deterioration.

Contrary to its 15-30% risk ratio in stroke, hypertension is the most important risk factor of intracerebral hemorrhages with very high mortality ratios of 25-60% [82]. In spite of the growing social awareness about hypertension, 72-81% of cases still have hypertension history [83]. The increase in prevalence of hypertension in aged people is the reason for the increased number of intracerebral hemorrhage in older adults. The cause of hemorrhage is impairment and rupture of the arterial wall as a result of hypertension. Arteriovenous anomaly and aneurysm are seen in people younger than 40, whereas the rupture of microangioma is seen between the ages of 40-70 [84]. The cause of recurrent lobar hematomas in normotensive people, older than 65, is cerebral amyloid angiopathy [85].

Hypertension should be a primary subject due to its part in the atherosclerotic process and its role in ethiopathogenesis of lacunar stroke and intracerebral hemorrhage. Meta-analyses of randomized controlled trials confirm an approximate 30-40% stroke risk reduction with the lowering of blood pressure [86]. Therefore, we should focus on the importance of not only the regular use of medications but also the regulation of dietary habits such as salt limitation and the prevention of a sedentary life style.

TREATMENT OF STROKE

Pathophysiology

Normal cerebral blood flow is 50 mL/100 g per minute. When an acute occlusion takes place in intracranial arteries, perfusion in cerebral tissue occupied in the distal of occlusion gets impaired and oxygen and glucose ratios decrease in brain parenchyma. If the perfusion pressure decreases too much, cerebral autoregulation becomes corrupted and cerebral blood flow becomes sensitive to the arterial blood pressure changes. If the cerebral blood flow decreases under 10 mL/100 g per minute, bioenergetic activities are rapidly lost, the membrane unity of neurons and surrounding glial tissue is lost, and the ion balance of the cell gets impaired. In the following process, sodium enters the cell, water inside the cell results in swelling of the cell, the calcium released by the internal calcium store is accumulated in the extracellular area and the accumulated calcium brings about the release of free radicals. Biochemical cascades are broken down via the released free radicals and necrosis of the cell occurs. In the case of a sharp decrease of cerebral blood flow, cell destruction can be seen via apoptosis without bioenergetic destruction. This area is called the ‘core’ tissue of the infarct and it is not possible to be saved with present treatments. When cerebral blood flow decreases

to levels between 10 mL/100 g/per minute and 20 mL/100 g/per minute, ion hemostasis and neuronal functions are lost, but the membrane units of the cells are preserved. The tissue in this area is regarded as recoverable tissue and is called penumbra. This area has recoverable tissue but cerebral blood flow must be quickly restored. In cases where cerebral blood flow decreases between 20 mL/100 g ile 50 mL/100 g per minute, neuronal functions are preserved. Cerebral tissue can tolerate these values for a long time without being destroyed, however, conditions such as hyperglycemia or hyperthermia can trigger the cell destruction. In an acute ischemic stroke, irreversible infarct tissues exist in the center and penumbra tissue, consisting of dizzy cerebral cells, in the periphery of this core area. The impairment of evoked potential waves and loss of neuronal functions in the penumbra area are shown, however, the penumbra area is accepted as a potential recoverable area via early recanalization. Beginning from the onset of the stroke, determining the core tissue and the recoverable tissue of the infarct is crucial for planning treatment strategies, and the ratio of the core/penumbra is a dynamic process. While core tissue increases from the beginning of stroke, recoverable tissues are exhausted in time [87].

THE TREATMENT OF ACUTE ISCHEMIC STROKE

The main purpose in acute stroke is to provide perfusion again. Intravenous thrombolytic treatment is one of the most important reperfusion strategies. It decreases death and disability. Intravenous thrombolysis is made by tissue plasminogen activator (tPA). The medication enables inactive plasminogen to be transformed into active plasmin. Plasmin is responsible for dissolving the fibrin plug. Intravenous thrombolytic treatment in patients with acute ischemic stroke was found to be reliable and effective both in randomized studies with controls and in international databases related to daily use. It has become the most important treatment strategy of recent years. Intravenous thrombolytic treatment remains important as the first choice in appropriate patients with acute ischemic stroke. If we define the reliability and efficiency criterion in pharmacokinetic terms, 1 in every 8 patients totally recovers, 1 in 3 patient partially recovers, and 1 in every 30 patients is harmed via this treatment. What is meant here by being harmed are the hemorrhagic complications and intracranial hemorrhages are the leading ones. It should be noted however, that all hemorrhages are not symptomatic and do not lead to death. After the efficiency of thrombolytic treatment was shown, studies related to lengthening the duration of the onset of treatment were planned in order to provide more patients with the benefits of the treatment. After the study of ECASS III, it was determined that intravenous thrombolytic treatment was efficient and reliable up to 4.5 hours. In this study, comparing the number of patients whose modified Rankin scores were between '0-1' and the group given the placebo, the number of patients in the rtPA group was found to be significantly higher. Even though intracranial and symptomatic hemorrhages were found to be higher in the treatment group, the death ratio appeared to be unreasonably higher in the placebo group. The results of the ECASS III study were immediately reflected to pilots, and the first 3 hours criterion was changed to 4.5 hours [88].

The recanalization rate with intravenous thrombolytic treatment is low, especially in cases with distal carotid T occlusion or proximal MCA occlusion with a high clot burden. From this point, endovascular treatment strategies were developed. In the study of PROACT,

investigating the efficiency of intra-arterial thrombolytic treatment following the first 6 hours after the symptom, it was demonstrated that pro-urokinase given as an intraarterial from a microcatheter provided 66% recanalization and significant increase compared to the placebo, with a ratio of 90 days of good prognosis. The efficacy of endovascular treatment was shown even if it was not approved by FDA. The studies of EMS, IMS I and II combining intravenous and intra-arterial treatments showed that a combined intravenous and intra-arterial treatment could also be reliable and efficient. Mechanical thrombectomy strategies were developed especially in cases resistant to intravenous treatment and contraindicated in pharmacological thrombolysis. Finally, almost 90% of the recanalization ratio was obtained via those mechanical approaches using retriever stent systems. The most important element for the achievement of a good clinical result is the case selection, regardless of the endovascular treatment approach [89].

Massive hemispheric brain infarcts such as malignant middle cerebral artery infarct have high death ratios (80%) due to different reasons such as cerebral edema, increased intracranial pressure, herniation and brainstem pressure. Decompressive hemicraniectomy surgeries are used for intervention of increased intracranial pressure irresponsive to conventional treatment methods in malignant middle cerebral artery infarcts and they have a life-saving effect on those conditions. Nevertheless, discussions about the appropriateness of surgical procedures and the criterions of patient selection are still not clarified. There are still unanswered questions remaining, such as the effect of the patient's age on the prognosis, the timing of surgery, the effect of hemispheric dominance, the size of the infarcted brain tissue and the monitorization of intracranial pressure. Although decompressive surgery was shown to lengthen the prognosis, the decision of decompressive hemicraniectomy for patients with massive brain infarct should be made depending on the patient.

ABSTRACT

A number of studies and meta-analyses have indicated that elevations in serum troponin levels are seen in up to 20% of patients with acute stroke. There is some evidence to suggest that newer highly sensitive troponin T assays may detect more cases of elevated troponin after stroke. Elevated troponin has been suggested as an independent predictor of outcome following acute stroke and there is certainly an association with both mortality and dependent status following stroke. However, the value of troponin as a predictor has been questioned and it does not perform as well as simple clinical measures of stroke severity or lesion volume in predicting outcome. The question of what causes troponin elevation in stroke is still uncertain and may be multifactorial. It has been shown that this rise is rarely due to underlying ischaemic heart disease, renal failure or other known causes of elevated troponin levels. An association with ECG changes and atrial fibrillation has been demonstrated. Frank myocardial ischaemia appears to rarely be the cause as measured by CK-MB. Troponin levels are certainly associated with the severity of stroke and the brain lesion volume. There is also some evidence to suggest that elevated troponin levels are more common in anterior infarcts involving the cortex supplied by the middle cerebral artery, particularly the insular region. A syndrome of sympathomimetic overactivity arising from the cardunculus in the insular region has been suggested as a possible cause of elevated troponin levels after stroke. A similar mechanism has been proposed for contraction-band necrosis and takotsubo cardiomyopathy both of which can be precipitated by psychological stress and are associated with troponin elevations. It has been proposed that infarcts in either

hemisphere may give rise to differential autonomic responses. However, to date the laterality of lesions associated with elevated troponin levels in acute stroke have been inconsistent. There remain a number of unanswered questions in the phenomenon of troponin elevations in stroke but this consistent finding demonstrates the close relationship between brain function and cardiac control. Further studies are required to delineate the likely causes of troponin elevations in individual cases and types of stroke, and to better understand the underlying pathophysiology. The final question remaining to be answered is whether or not any specific intervention might prevent or alleviate the presumed myocardial injury and lower any associated mortality and morbidity.

Keywords: Stroke, troponin, ischaemic, haemorrhagic, outcome, meta-analysis, review

1. INTRODUCTION

Worldwide, stroke is the second most common cause of death and accounts for 9% of all deaths [137]. Stroke is also a significant cause of morbidity and disability, being associated with the second highest impact in terms of disability-adjusted life years [132]. Whilst there is some evidence to suggest that in the developed world prevention strategies may be having a significant impact in reducing the incidence of stroke [53], this is likely to be more than offset by a well-documented ageing of these populations [132].

When assessing patients with acute stroke, accurate predictors of both short term and long term outcome would be of immense value in planning both acute treatment and longer term rehabilitation strategies. Clinical [140] and imaging data [61] have been found to be of relatively limited value in the acute setting, although repeat measures may be of more value. The finding of elevations of serum troponin, a marker of myocardial injury, in a small but significant proportion of patients presenting with acute stroke and the association of this elevation with a poor prognosis a little over 10 years ago [101] therefore held out great promise for a serological marker of stroke severity and outcome, available at the time of admission. The finding of elevations in serum troponin levels in acute stroke has also raised significant questions as to precisely what is the relationship between the mind (brain) and the heart in this setting. In this chapter we aim to distil the available evidence for the relationship of the mind and heart in the context of acute stroke and troponin levels.

Whilst a clear relationship exists between stroke and troponin, its nature is complex and the predictive value of elevations in troponin T and I is limited. What is more intriguing is the nature of the relationship and the light that this may shed on the aetiology of stroke and the factors which lead to a poor outcome following stroke. Thus, the overall purpose of this review is to critically analyse the available data with regards to factors associated with elevations in troponin levels in the acute stroke setting and look at the potential mechanisms involved with a view to further developing management strategies.

2. METHODS

2.1. Review of the Literature

A systematic search of databases (Cochrane, MEDLINE, PubMed) was conducted using the search terms: stroke; cerebral infarction; intracerebral haemorrhage; cerebrovascular accident and troponin. Searches were confined to the title and abstract. Only articles with abstracts in English were included. The initial search yielded 338 articles. Abstracts were reviewed and potential studies of relevance identified. Studies were only included if clear inclusion and exclusion criteria were given and raw data with respect to the frequency of serum elevations of troponin were provided. Studies were excluded if: subject recruitment was non-randomly selective (e.g., fourth generation troponin T negative cases excluded; 1 study) [108]; only cases with subarachnoid haemorrhage were included (8 studies) [57, 94, 124, 148, 181, 194, 205, 206]; or if raw data were not provided (4 studies) [28, 89, 174, 213]. Bibliographies of relevant studies and relevant reviews were screened to identify additional potential studies. Other references were identified from the authors' personal knowledge and review of relevant articles.

2.2. Statistical Analysis

For comparison of categorical data odds ratios (OR) with 95% confidence intervals (CI) were used and a χ^2 test was applied to give p-values where appropriate. For continuous variables, because in the majority of comparisons only means and standard deviations were available rather than raw data, a student's t-test for comparison of means was utilised. Whilst some of the measures compared were unlikely to have been normally distributed, because of the generally large sample sizes and lack of significant skew (as judged by medians) this compromise was felt to be acceptable. Where medians and a range were provided, a mean and standard deviation were estimated using standard methods [93]. P-values of < 0.05 were accepted as being statistically significant. No correction for multiple testing was applied.

For assessment of the predictive value of clinical features with regards to outcome, sensitivity and specificity with positive and negative predictive values and likelihood ratios were calculated using the Toronto University evidence-based medicine online statistics calculator [192]. This software also provides estimates for 95% CI.

The principal outcome measures identified were death and death or dependency, most commonly assessed using the modified Rankin scale [25]. Comparisons of outcome were performed using RevMan v5.2 [168]. An I^2 value of less than 25% was taken to indicate low heterogeneity suitable for analysis by fixed effects models otherwise random effects models were applied [88]. Comparisons of frequencies were similarly performed using generic inverse variance methods and entering frequencies and standard errors as natural logs. Funnel plots were used to assess for publication and other bias using standard error on the vertical axis which allows for plotting of 95% CI as straight lines [191]. For the meta-analysis of multivariate adjusted odds ratios natural log of the standard error was estimated by dividing the difference in the natural log of the quoted 95% CI by 3.92. Where confidence intervals were not provided standard error was estimated from a contingency table based on the quoted

adjusted odds ratio and the given frequencies of cases and controls, and the number of unfavourable outcomes.

3. TROPONINS

3.1. Troponin Structure, Function and Metabolism

The basic contractile apparatus of myocytes are the myofibrils [97]. Each myofibril is composed of thick and thin filaments. Thick filament is composed of myosin and the troponin protein complex is immobilized on the thin filament of the contractile apparatus of the muscle. [52]. The troponin protein complex consists of three subunits, namely troponin C, I and T [161]. The function of the troponin complex is to modulate contractile function of the sarcomere in response to cytosolic calcium. Thus, the troponin complex plays a critical role in the regulation of excitation–contraction coupling in the heart. Cardiac troponin C is identical to its skeletal isoform, does not have cardiac specificity and thus is not used in assays for the diagnosis of cardiac injury [197]. Troponin I is not expressed in skeletal muscle or other tissues during development [201] and is highly specific for myocardium. Monoclonal antibodies can distinguish the cardiac troponin T isoform from skeletal isoforms without cross-reactivity, allowing the conclusion that elevation of troponin T in serum originates from myocardium and always reflects myocardial injury of some form. Assays currently used to measure troponin T levels have cardiac specificity equivalent to that of assays for troponin I [196]. Troponins have cytosolic and structural pools. Release of troponin occurs first from the early appearing cytosolic pool and subsequently from the structural pool. Approximately 6–8% of intracellular cardiac troponin T has been reported to exist in a cytoplasmic form [117]. Troponins exhibit characteristic biphasic release kinetics following myocardial injury. Release from the cytoplasmic pool gives rise to peak serum concentrations 24–36 hours after injury, and structural protein release leads to a second blunted peak 2–4 days after injury. Troponin initially released from the cytosolic pool has a half-life in serum of about 2 hours. Continuing breakdown of the myofibrillary-bound complex of troponin and actin explains the prolonged elevation of serum troponin after myocardial injury [138]. Troponin remains increased in serum for 7±10 days [117].

Transient troponin release may be due to reversible forms of myocardial injury. Transient elevation in experimental models of vital exhaustion and in some exercise studies may be due to the release of troponin from the cytosolic pool only [151]. The failure of continuing release has been attributed to the lack of release of structurally bound troponin, commonly observed after irreversible injury to the myocardium [35].

3.2. Troponins As a Marker of Cardiac Ischaemia

Troponin is a highly sensitive biomarker of myocardial injury that is used in the diagnosis of acute myocardial infarction and for risk stratification of patients with acute coronary symptoms [115]. In 2000 a joint committee of the European Society of Cardiology and the

American College of Cardiology issued new criteria that acknowledged that elevations in biomarkers were fundamental to the diagnosis of acute myocardial infarction [7].

Troponin is very sensitive in the detection of myocardial injury from any underlying cause including acute myocardial infarction [199]. In most situations an elevated troponin level also indicates an adverse prognosis [82, 164]. Although troponin is highly sensitive for detection of cardiac injury, it lacks specificity for the diagnosis of myocardial infarction and can be elevated in a number of other conditions including sepsis [211], heart failure [47], renal failure [80], pulmonary embolism [70], tachyarrhythmias [180], cardiac trauma [3], pericarditis [26] and a number of other conditions [152]. Below is a review of some of the commoner pathologies other than acute coronary syndrome that can cause troponin elevation with an emphasis on those that may be relevant to stroke.

3.3. Troponins As a Marker of Other Pathologies

Measuring circulating troponin using highly sensitive assays has become the gold standard approach in diagnosing acute myocardial infarction. However, increased troponin levels are found in several other conditions.

3.2.1. Sepsis and Septic Shock

The cardiovascular system is frequently compromised by sepsis and always affected by septic shock. Although a number of mediators and pathways have been shown to be associated with myocardial depression in sepsis, the precise cause remains unclear. A high incidence of abnormal troponin levels in patients with sepsis (between 31%-85%) have been described, most in the absence of coronary artery disease on angiography [8, 16, 112, 188, 210]. There is some correlation of levels to the presence of left ventricular dysfunction as measured by echocardiography and a higher need for inotropic support [210]. There is also an association with lower survival rates [221]. The cause of troponin elevation in sepsis is probably multifactorial. It has been suggested that inflammatory cytokines released from neutrophils, particularly Tumour necrosis factor- α (TNF- α) and Interleukin-6 are responsible for direct myocardial depression and increased cell membrane permeability to troponin molecules in sepsis [225]. Decreased myocardial perfusion due to hypotension, increased oxygen consumption due to tachycardia, release of noradrenaline and adrenaline with subsequent vasoconstriction, and increased coagulation of the capillary bed have all been proposed as playing a significant part in myocyte damage and subsequent troponin release [112]. Cardiac toxins are another possible mechanism [109].

3.2.2. Pulmonary Embolism

For risk stratification of haemodynamically stable pulmonary embolism patients, current consensus guidelines of the American Heart Association recommend routine assessment of right ventricular function by cardiac biomarkers and echocardiography [100]. Serum troponins are elevated in up to 50% of patients with pulmonary embolism [222]. A positive troponin test is an important prognostic marker in pulmonary embolus, and predicts right ventricular dilatation and an increased number of segmental perfusion defects on lung scintigraphy [142]. These patients had higher risk of developing complications including in-

hospital death, prolonged hypotension, cardiogenic shock, inotropic support and mechanical ventilation. Moreover, after adjustment, an increased troponin T value was an independent predictor of 30 day mortality in pulmonary embolus. It has been suggested that troponin estimation may be used to help risk stratify patients with pulmonary embolus thereby allowing targeted use of more aggressive treatment [190]. In a study involving 64 normotensive patients with pulmonary embolism, troponin T was detected in 50% of patients [72]. All 8 in hospital deaths occurred in the troponin T positive group (OR 21; 95% CI 1.2 to 389). Increased troponin T was the only parameter predicting 15 in hospital adverse events (death, thrombolysis, cardiopulmonary resuscitation, inotropic support) [72]. Recently, pulmonary embolism has been reported as the most common non-acute coronary syndrome cause of increased troponin levels [99]. Release of troponin in pulmonary embolism is attributed to the combination of acute pressure overload within the right ventricle, impaired coronary artery flow, and the hypoxic state generated [70].

Pulmonary embolism is a recognised complication of stroke, but in general this does not occur until after a median delay of 20 days from when immobility is imposed at the onset of stroke [214]. Very occasionally, pulmonary embolism and stroke can occur simultaneously as a result of embolisation of a deep vein thrombosis to both the lungs and the brain through a patent foramen ovale [162].

3.2.3. Cardiac Failure

Troponin elevation is seen in up to 49% of patients with congestive cardiac failure [92] and is associated with an adverse outcome in terms of mortality and cardiovascular events [147]. There is a close correlation between troponin levels and N-terminal prohormone of brain natriuretic peptide (NT-proBNP) levels in cardiac failure suggesting that the cause of troponin leak is due to cardiac strain [130]. Troponin levels are also useful in staging and prognostication for cardiac failure [6]. *In vitro* experiments with myocytes have demonstrated a link between myocardial wall stretching and programmed cell death [36]. Studies in isolated rat hearts have shown troponin degradation in response to increased preload independent of any ischaemia. Activation of the rennin-angiotensin and sympathetic systems may further compound the myocardial injury [109]. Congestive cardiac failure is an independent risk factor for stroke and higher mortality in the setting of stroke [102]. Cardioembolic stroke seems to be the most commonly associated mechanism, such that formal anticoagulation has been advocated [69]. Studies in acute stroke have demonstrated a clear association between the presence of cardiac failure and an elevated troponin, and an inverse correlation between troponin level and left ventricular ejection fraction (LVEF) [13]. NT-proBNP is also elevated in a significant number of acute stroke patients and is associated with a worse prognosis [169]. Whilst the evidence for a relationship is clear, what remains to be determined is which is chicken and which is egg?

3.2.4. Renal Failure

Cardiac troponins are frequently elevated in the absence of acute coronary syndrome among patients with varying degrees of renal failure, and troponin T is more frequently increased compared with troponin I in asymptomatic patients with end-stage renal disease [14]. Troponin T elevation is seen in approximately 53% of patients with renal failure compared with only 7% for Troponin I [62]. In addition, the prevalence of increased serum troponin T and troponin I increased with increasing severity of kidney disease. The

mechanisms for increases in troponin T concentrations in patients with kidney disease are not clear. There is emerging evidence that increases in troponin T in asymptomatic patients with end-stage renal disease indicates subclinical myocardial necrosis or injury [155]. There is robust evidence that troponin T is a powerful prognostic marker in end stage renal disease [49]. The reason for elevations in troponin levels in renal failure appear to be due to either an associated cardiomyopathy or silent coronary artery disease rather than any effect of impaired renal function on the clearance of troponins which are principally cleared via the reticuloendothelial system [62].

4. TROPONINS IN STROKE

A total of 29 observational studies in a variety of settings looking at the frequency of elevations in serum troponin levels with a variety of cut-offs and assays for both troponin T and troponin I were identified. Whilst many of the studies collected data prospectively, the core study design was essentially retrospective for all. A summary of included studies is provided in Table 1. Five previous meta-analyses or systematic reviews of earlier studies were identified [1, 104, 105, 110, 118] and an extension to these incorporating studies looking specifically at intracerebral haemorrhage and studies performed since 2009 is provided in Figure 1. The overall estimate for the frequency of serum elevations in troponin level for acute stroke was 10.85% (95% CI; 9.88 – 11.82). When analysis was restricted to studies which did not exclude known causes of troponin elevation the figure was 11.0% (95% CI; 9.18 – 13.22). The I^2 figure for heterogeneity was 0% and therefore the use of a fixed model was appropriate. However, there was wide variation depending upon the type of troponin measured, the cut-off used and the types of stroke included. The type of stroke has a significant effect upon the frequency of troponin elevation, with haemorrhagic stroke being more commonly associated. Relevant data are summarised in Table 2 and indicate that elevations in serum troponin levels are almost twice as common in haemorrhagic stroke than ischaemic stroke. The frequency of troponin elevation in the studies where both haemorrhagic and ischaemic stroke were included was closer to the figure for haemorrhagic stroke than ischaemic stroke which is surprising given the relatively low frequency of haemorrhagic stroke in these studies. There was some evidence for publication bias in the studies of ischaemic stroke (Figure 2). For studies of haemorrhagic stroke and all stroke there may also be some evidence of bias but the smaller number of studies and a lack of larger studies makes it difficult to draw any firm conclusions. However, the overall effect estimate was representative of the largest studies reported suggesting that despite possible publication bias these overall estimates of troponin elevation frequency in stroke are accurate. There was no clear pattern of change in the frequency of troponin elevation in stroke over time, if anything there appears to have been a fall in the frequency of troponin elevations over time, perhaps reflecting an increase in specificity with improvements in the assays used (Figure 3). However, this trend is not significant. Similarly for both troponin T and troponin I the cut-off used does not appear to show any consistent trend in the frequency of finding an elevated level (Figure 4).

Figure 1. Meta-analysis of studies of frequency of serum troponin elevation in stroke.

However, it should be noted that several generations of troponin assays have been used across these studies and the particular tests used also varied. The frequency of elevated troponin I levels were in general higher than troponin T. It has also been demonstrated that troponin I levels in patients with acute ischaemic stroke are elevated when compared to age and gender-matched healthy controls [98].

4.1. Clinical Associations of Troponin Elevation in Acute Stroke

Table 3 shows the collected data, where this was available, from all of the studies analysed with regards to clinical features evident at initial assessment. This included demographic data, past history, ECG assessment, neurological assessment and imaging data. In addition to the type of stroke being associated with elevations of serum troponin as discussed above, age is also related. Patients with acute stroke and a troponin rise are generally older. In this univariate analysis evidence of myocardial ischaemia on ECG or atrial fibrillation (prior to or on presentation) was associated with troponin elevation. As has been noted previously congestive cardiac failure and renal failure were both associated. Suspected cardioembolic aetiology and involvement of the insular cortex were also statistically significant. Interestingly, crude measures of stroke severity such as the Glasgow coma scale and other measures of level of consciousness were not significant, but the numbers were small. Conversely, the National Institutes of Health Stroke Scale (NIHSS) and the Scandinavian Stroke Scale (SSS) scores were both significantly associated.

Table 2. Frequency of troponin elevation in different stroke types

Type of stroke	Frequency of Troponin Rise		P-value
	N	(%)	
Haemorrhagic	590	(18.84)	
Combined	852	(18.54)	
Ischaemic	4320	(10.46)	<0.0001

The association with ischaemic features on ECG is to be expected and an increased frequency of such changes has been reported previously in the setting of acute stroke [29]. What is more difficult to determine is the cause of these changes. Acute myocardial infarction (AMI) appears to be an infrequent cause of troponin elevation but the diagnosis of AMI in this setting is not easy. Many studies excluded AMI and the criteria utilised to diagnose AMI were generally a combination of clinical symptoms, evolving ECG changes and serological markers. Only a few studies systematically looked for AMI and even then the frequency in subjects with elevations of troponin serum levels was only 6%. Interestingly, the frequency of AMI in the troponin negative group was 4% although many studies included AMI within the previous 2 weeks. What is clear is that frank myocardial infarction is an uncommon cause of troponin elevation in acute stroke. Lesser degrees of ischaemic changes on ECG may relate to prior ischaemic heart disease, current acute coronary syndromes and cardiac strain caused by arrhythmias or failure. There is clear evidence from the available data for all of these factors. However, even after excluding cases of renal failure the cause for troponin rise in acute stroke remains uncertain in the majority of cases [21].

SE = standard error.

Square indicates highly sensitive troponin T study. Linear trend lines plotted using least squares method.

Figure 4. Frequency of troponin T and I elevations determined by cut-off used.

The association with stroke severity is similarly complex. Most studies have also shown an association with lesion volume for both ischaemic and haemorrhagic stroke [13, 68]. The association with cardioembolic stroke does suggest that the cause of troponin rise may be related to cardiac pathology. However, cardioembolic strokes are generally more severe [33] and therefore this apparent association could be an artefact. This aetiology has not emerged as an independent risk factor for troponin rise from multivariate analyses, but not all studies incorporated aetiology in the model and sample sizes were generally small.

Involvement of the insular region is an intriguing finding which has been commented on previously particularly in the context of sympathomimetic cardiac stress as a cause of troponin rise in stroke [187].

This will be discussed in more detail below but suffice to say that there is also a relationship between involvement of the insular and large middle cerebral artery stroke [60]. Thus this finding may also be an artefact. There is also a high likelihood of confounding between atrial fibrillation and cardioembolic aetiology, as these two factors are clearly related. The format of the data utilised in this analysis do not permit exploration of interactions through multivariate analysis.

Table 3. Associations of clinical features with elevated troponin at presentation

Clinical Feature	All			Normal Troponin			Elevated Troponin			OR	95% CI	t	P-value
	n			n			n						
N		5559			4620			939					
Demographic Data

OR = odds ratio; CI = confidence interval; NIHSS = National Institutes of Health Stroke Scale; SSS = Scandinavian Stroke Scale; SD = standard deviation.

4.2. Troponin and Other Markers of Cardiac Disease in Acute Stroke

4.2.1. Serological Markers

Troponin T has been shown to be less frequently elevated in acute stroke when compared to both creatinine kinase (CK) and CK-MB isoenzymes with clear evidence that troponin levels can remain completely normal despite significant elevations of these enzymes [20]. It has been concluded that elevations in CK and CK-MB may arise in acute stroke as a result of skeletal muscle lysis because of trauma, prolonged prostration or a combination of relative dehydration and starvation. This notion is supported by the finding of concomitant elevations of myoglobin in a pattern which follows the elevations of CK/CK-MB over about a five day period [20]. This contrasts with the pattern of troponin elevation typically seen in stroke which is generally a tonic elevation lasting for at least the first 5 days [20, 107]. A detailed study of degradation patterns of troponin I has suggested that troponin I elevations in acute stroke have the same origin as those seen in myocardial infarction, indicating that the troponins seen are indeed of cardiac origin [106]. Correlations between troponin levels and both CK and lactate dehydrogenase levels have been demonstrated [13].

Elevations in NT-proBNP have also been described in the setting of acute stroke [58, 81, 98]. This neurohormone is released from ventricular myocytes in response to ventricular pressure and volume overload. NT-proBNP acts via the rennin-angiotensin-aldosterone system, endothelin and sympathetic outflows to cause vasodilatation as well as fluid and water excretion in the kidneys [71]. In the setting of acute stroke NT-proBNP elevations are more common than troponin leak [58] and appear to predate the peak of troponin and CK elevations by approximately 48 hours [98]. In general use, NT-proBNP is a valuable marker for cardiac failure [134]. In one study the levels of NT-proBNP were statistically significantly associated with serum troponin levels ($r = 0.29$) and inversely associated with LVEF ($r = -0.67$) [98] suggesting that left ventricular failure may be part of the explanation for troponin elevations in acute stroke. However, the correlation coefficient between NT-proBNP and troponin was low (0.29) and elevations of NT-proBNP in acute stroke are significantly more common (65%) [58] compared with troponin (11%) in the meta-analysis presented in this chapter. One study has suggested that NT-proBNP is an independent predictor of outcome even when troponin and stroke severity (NIHSS) were included in the model [81], but two larger studies failed to demonstrate any independent predictive value of NT-proBNP with regards to outcome [58, 98]. Cardiac failure is an independent predictive factor following stroke [144] and this was also identified in one of the studies of NT-proBNP [58].

4.2.1. ECG Findings

A summary of specific ECG findings from the studies evaluated is provided in Table 4. This confirms the previously noted association between atrial fibrillation and elevated troponin.

What is also highlighted is the fact that there seems to be an additional association with new onset atrial fibrillation (OR 5.4; 95% CI; 1.85 – 15.82). It is noteworthy that in the data from studies looking only at haemorrhagic stroke [136] the association with atrial fibrillation was not apparent, although the numbers were small. The finding of an association between troponin rise in stroke, particularly ischaemic stroke, and atrial fibrillation adds to the notion of a connection between troponin rise and a cardioembolic cause of the stroke. The fact that atrial fibrillation is not a factor in troponin rise associated with haemorrhagic stroke suggests

that the mechanism in ischaemic stroke is more likely to be through the association of cardioembolic stroke with larger infarcts and greater stroke severity.

Table 4. ECG associations with elevated serum troponin in acute stroke

ECG Feature	Normal Troponin		Elevated Troponin		OR	95%CI	P-value
	n/N	(%)	n/N	(%)			
Atrial fibrillation	103/782	(13)	44/147	(30)	2.82	(1.87 - 4.24)	<0.0001
New onset AF	12/250	(5)	6/28	(21)	5.41	(1.85 - 15.82)	0.003
Old infarct	52/369	(14)	14/88	(16)	0.97	(0.51 - 1.83)	0.947
Current infarction	13/438	(3)	9/78	(12)	4.26	(1.76 - 10.35)	0.002
Ischaemic changes	211/1027	(21)	75/206	(36)	2.21	(1.61 - 3.05)	<0.0001
Prolonged QTc	5/39	(13)	0/10	(0)	0.3	(0.02 - 5.86)	0.756
RBBB	35/301	(12)	10/59	(17)	1.55	(0.72 - 3.34)	0.36
LBBB	13/439	(3)	7/93	(8)	2.67	(1.03 - 6.88)	0.071

AF = atrial fibrillation; RBBB = right bundle branch block; LBBB = left bundle branch block.

There is again an association between troponin elevation and both current acute myocardial infarction and ischaemic ECG changes. However, the frequency of myocardial infarction as a cause of troponin rise is low (12%) and is clearly not the cause of troponin leak in the majority of acute strokes. The situation is further complicated by the finding that ST elevation in the setting of subarachnoid haemorrhage was associated with normal coronary vessels at angiography [121] indicating that the frequency of myocardial infarction may be overestimated in these settings. Evidence of old infarction, prolongation of the QT interval and bundle branch block (right and left) were not associated with elevated troponin levels. Prolongation of the QT interval has been previously shown to be an independent predictor of death following stroke [89] and in a multivariate analysis both prolonged QT and elevated troponin were independent predictors of death or dependence, as measured by the modified Rankin scale [65].

4.2.1. Echocardiography

Four studies have specifically looked at the results of echocardiography in relation to troponin elevations in acute stroke [13, 34, 45, 98]. A significant association between troponin elevations and wall motion abnormality on echocardiography has been described in one recent study [45]. An inverse correlation between LVEF and troponin level has been found ($r = -0.53$; $p < 0.0001$ [13]. Combining two studies which looked at LVEF in acute stroke the mean for patients with elevated troponin was significantly lower ($52.1\% \pm 8.7\%$) than in those with normal troponin levels ($61.0\% \pm 4.8\%$; $p < 0.0001$) [13, 98]. Similarly, using a cut-off of LVEF $< 50\%$ troponin elevation was seen in 11/29 (18%) patients with reduced LVEF versus 22/122 patients with normal LVEF ($p = 0.037$) [13, 34]. No association with left atrial enlargement, left ventricular hypertrophy or focal hypokinesis was seen [34].

4.3. Troponin and Lesion Characteristics in Acute Stroke

Detailed analysis of lesion characteristics on imaging has been undertaken in a number of studies of troponin elevation in acute stroke [13, 34, 67, 68, 98, 136, 187]. A summary of the findings from these studies is given in Table 5.

Table 5. Lesion locations of strokes with and without troponin elevation

Lesion Location	Normal Troponin		Elevated Troponin		OR	95% CI	χ^2	P-value
	n/N	(%)	n/N	(%)				
Cortical								
Frontal/parietal/temporal (MCA/ACA)	176/507	(35)	32/67	(48)	1.719	(1.029 - 2.872)	3.814	0.051
Occipital (PCA)	24/507	(5)	5/67	(7)	1.623	(0.598 - 4.408)	0.438	0.508
Insular	83/468	(18)	20/57	(35)	2.507	(1.385 - 4.539)	8.633	0.003
Basal ganglia/internal capsule (lacuna)	183/507	(36)	14/67	(21)	0.468	(0.253 - 0.866)	5.409	0.02
Posterior fossa (brainstem/cerebellum)	114/468	(24)	15/57	(26)	1.109	(0.593 - 2.074)	0.026	0.872
Dominant	111/238	(47)	19/36	(53)	1.279	(0.634 - 2.581)	0.259	0.611

MCA = middle cerebral artery; ACA = anterior cerebral artery; PCA = posterior cerebral artery; OR = odds ratio; CI = confidence interval.

Troponin elevation is associated with lesions in the frontal, parietal and temporal cortex (middle cerebral artery and anterior cerebral artery territories for ischaemic strokes) and specifically with the insular region as noted previously.

Conversely there was a lower risk of troponin elevation for lesions of the basal ganglia and internal capsule (lacuna infarcts). There was no association with occipital or posterior fossa infarcts (both posterior cerebral artery territory) and there was no clear pattern in terms of laterality of stroke.

Again posterior circulation strokes tend to be small in volume and less dramatic in terms of their clinical manifestations. Similar trends for lesion location associations were seen for the one study of haemorrhagic stroke [136] as compared to the results for ischaemic stroke.

Greater lesion volume also shows an association with elevated troponin levels with the mean ($\pm$ SD) volume for cases with elevated troponin being 75 ml ($\pm$ 56 ml) and for those with normal troponin levels being 35.7 ml ($\pm$ 72.1 ml; $p = 0.0044$).

4.4. Troponin As an Outcome Predictor in Acute Stroke

In univariate analyses of predictors of outcome following acute ischaemic stroke, elevations of serum troponin T have consistently emerged as being positively associated. A meta-analysis of available data using both death or death and dependence as the outcomes of interest demonstrate an odds ratio for troponin elevation of around 3.5 and 2.5 respectively (Figures 5 and 6).

Funnel plots for these data, whilst widely spread for the death outcome data, show no evidence for bias in either case (Figure 7). A typical survival plot for elevated troponin against normal levels from our own data is shown in Figure 8.

In multivariate analyses troponin elevation has emerged as an independent predictive factor for outcome in 12 out of 16 studies [18, 22, 41, 48, 51, 58, 65, 67, 68, 81, 86, 89, 101, 107, 178, 213]. However, in 3 of these studies no measure of stroke severity or lesion volume was included in the model [18, 65] and in 3 others only crude measures of severity such as GCS and lesion volume were included [67, 86, 101].

As demonstrated earlier, the association of such crude measures of stroke severity with troponin elevation is not significant and thus may not accurately reflect the potential confounding effect of stroke severity. In studies where the NIHSS or SSS were utilised in the multivariate analysis, troponin emerged as an independent predictor in 7 out of 11 studies, this was generally seen in the larger studies.

The NIHSS and SSS are generally found to be independently predictive even in the smaller studies [41, 68, 81]. It is evident that troponin levels are not as helpful as stroke severity measures. A meta-analysis of pooled adjusted OR for death as the outcome gives 2.90 (2.13 – 3.95) and for death or dependence 2.30 (0.90 – 5.85) as shown in Figure 9. For death as the outcome, when studies without a clinical measure of stroke severity are removed the OR falls to 2.44, but the confidence intervals still exceed 1.0 (1.72 – 3.46).

b

Figure 9. Forest plots of troponin elevation predicting (A) death and (B) death or dependence outcomes in multivariate analyses.

Analysis of the value of these factors in predicting outcome in terms of sensitivity and specificity are summarised in Table 6. The overall sensitivity of elevated troponin in predicting death was low at 39.4% (95% CI; 35.1 – 43.8%) and this finding was consistent across all types of stroke. However, the specificity was reasonably high at 84.2% (95% CI; 82.7 – 85.5%). The positive likelihood ratio is relatively low at 2.49 but the 95% CI do not cross 1 (2.16 – 2.86) indicating that testing troponin levels in stroke is helpful in predicting death. The negative predictive value is also helpful at 88.4% (95% CI; 87.0 – 89.6%). The figures for death or dependency were similar but generally less impressive with sensitivity of 28.2% and specificity of 86.9% with wider confidence intervals owing to the smaller number of studies which included this outcome measure. It is noteworthy that the comparable figures for an NIHSS score greater than 14 in the prediction of death as an outcome for acute stroke are a sensitivity of 78% (95% CI 58 – 90%) and specificity of 96% (95% CI; 88 – 99%) with a positive likelihood ratio of 17.1 (95% CI, 5.8 – 54.8). Assuming an overall mortality figure of 15% for acute stroke, which is the figure seen for the studies included in this chapter, then the post-test probability for elevated troponin is approximately 25%, whereas for an NIHSS score greater than 14 on admission the post-test probability of death is approximately 70%.

CI = confidence interval; Sens = sensitivity; Spec = specificity; PPV = positive predictive value; NPV = negative predictive value; LR+ = positive likelihood ratio.1.

One recent study using a highly sensitive troponin T assay has suggested that this test may be of more value in predicting outcome when compared to a fourth generation troponin T assay [66]. However, another study using the same assay in stroke patients who were negative for a fourth generation troponin T assay showed no additional predictive value for the more sensitive assay despite identifying troponin elevations in 65/193 (33.7%) of apparently troponin negative patients on the standard assay [108]. A recent study of a wide range of biomarkers in a large cohort of subjects showed no additional predictive value over and above clinical measures for any of the assays, which included troponin T [213].

The commonest causes of death following stroke in the acute phase are complications of the stroke and recurrent stroke (approximately 85%), but after one year cardiovascular disease is the commonest (approximately 55%) [83]. In one study of troponin elevations in acute stroke cause of death was analysed and although the numbers were small 4/9 (44%) of deaths in the group with elevated troponins were cardiac deaths compared with 1/4 (25%) of patients without troponin elevations. This result was not statistically significant but the numbers of cardiac deaths in the normal troponin group is similar to that expected from larger studies of stroke survival in the acute phase. This suggests that troponin elevations are related to cardiac injury and an increased risk of cardiac death as a consequence.

5. MECHANISMS OF TROPONIN RISE IN ACUTE STROKE

5.1. Myocardial Infarction

From the data presented in this chapter it is clear that troponin rise in acute stroke is due to myocardial infarction in a minority of cases (around 12%). In the largest single study of troponin levels in stroke the estimated frequency of myocardial infarction within the preceding 2 weeks for those with an elevated level was 8/73 (11%) [21]. These figures are consistent with a previous estimate [104]. The fact that the difference in the frequency of troponin elevation in acute stroke was only marginally different when studies that excluded myocardial infarction and other known causes of troponin elevation were removed also suggests this is a relatively uncommon cause. Myocardial infarction is a well-recognised cause of stroke [208]. A recent meta-analysis has shown that the in-hospital risk of stroke following acute myocardial infarction is 14.5% [216]. The purported mechanisms include emboli from arrhythmias (most notably atrial fibrillation) as well as intraventricular thrombus associated with ependymal infarction [207], altered flow dynamics due to focal hypokinesia [131] or a ventricular aneurysm [133]. A prothrombotic state may also lead to the co-occurrence of both pathologies [198]. Myocardial infarction may also precipitate cardiac failure and is associated with a number of physiological responses which can lead to a prothrombotic tendency which might contribute to the heightened risk of stroke [30, 202]. It is pertinent to note that haemorrhagic stroke is less common than ischaemic stroke as a complication of myocardial infarction, yet troponin elevation is more commonly seen in haemorrhagic stroke compared with ischaemic events. It therefore seems likely that it is the severity of the cerebral insult that is important in generating a troponin rise. This possibility has been noted previously [118]. It has been postulated that very high troponin elevations are generally indicative of acute myocardial infarction in the acute stroke setting, but a precise

cut-off has not been determined. Early revascularisation in the setting of acute coronary syndrome has been shown to reduce the risk of subsequent stroke independently of the size of infarct or the presence of cardiac failure [209].

5.2. Renal Failure

Renal failure may be a predisposing factor for troponin elevation in up to 30% of acute strokes, but severe renal failure as a sole cause of troponin elevation is rare in stroke [21, 68]. Because of this, it is not possible to comment on the causal mechanism. Renal failure may simply predispose to an increased risk of stroke through hypertension and other mechanisms whilst also causing a background elevation in troponin levels as presented earlier in this chapter. The possibility of an increased risk of cardioembolic stroke due to cardiac failure cannot be excluded as a possible mechanism for the association.

5.3. Infective Endocarditis

Bacterial and other forms of endocarditis are occasional causes of acute stroke [84, 159]. Troponin elevations in stroke have been noted to be associated with elevations of C-reactive protein levels which can be a sign of infection, underlying arteritis and ischaemic inflammation [203]. However, it seems unlikely that bacterial endocarditis and associated cardiac failure or sepsis are responsible for troponin rise in anything other than occasional cases. One retrospective study identified 27 cases of definite infective endocarditis (modified Duke criteria [127]) as a cause of stroke over 7 years in one centre [56]. The majority of cases of endocarditis were diagnosed after the onset of stroke symptoms. No denominator was provided but these figures would suggest a co-occurrence of endocarditis in no more than a few percent of cases of stroke.

5.4. Pulmonary Embolism

Pulmonary embolism was identified as a possible cause of troponin rise in acute stroke in 1/73 cases in one series [21]. Again this must be only an occasional cause of troponin rise in acute stroke.

5.5. Serious Arrhythmias

Serious tachyarrhythmias are seen in only a small proportion of patients with acute stroke (around 1%) [215]. It therefore seems unlikely that this is a common cause of troponin elevation in acute stroke. Whilst a number of conduction abnormalities and atrial fibrillation have been identified amongst patients with elevated troponin levels in acute stroke, tachyarrhythmias have generally not been observed [48, 65, 89, 203].

5.6. Cardiac Failure

A background of ischaemic heart disease and congestive cardiac failure is clearly important and it seems likely that current cardiac failure is the cause of troponin rise in perhaps 40% or so of cases. There is supporting evidence for this from a study indicating an association between troponin elevations in acute stroke and lower haemoglobin level, haematocrit and white blood cell count [48], which could be explained by the haemodilution effect of cardiac failure [11]. Cardiac failure is also a well-recognised cause of stroke with a cumulative incidence of around 16% after a little over 4 years [217]. The suggested mechanisms are again ventricular thrombus formation and hypercoagulability.

Cardiac failure and left ventricular failure associated with pulmonary oedema is well recognised in subarachnoid haemorrhage indicating that this phenomenon can arise as a result of extreme generalised cerebral insult [42]. Cardiac failure is also associated with an increased risk of recurrent stroke due to cardioemboli [102] and it seems likely that relative hypoperfusion due to cardiac failure would be associated with a greater extent of infarction in the ischaemic penumbra of ischaemic stroke. Cardiac failure is certainly associated with an adverse outcome in stroke [183] and also predisposes patients to a number of other cardiac and non-cardiac complications which would contribute to an increased risk of death and a poorer prognosis.

5.7. Other Possible Causes of Troponin Rise in Acute Stroke

After excluding frank myocardial infarction, serious arrhythmias, endocarditis, pulmonary embolism and renal failure the cause of troponin rise remains unexplained in over half of cases.

5.7.1. Atrial Fibrillation

The meta-analysis presented in this chapter indicates that atrial fibrillation is seen in roughly one third of cases of acute stroke with elevated troponin and also suggests that the association with new onset atrial fibrillation is higher. A previous study looking specifically at atrial fibrillation found an association between troponin elevation and new onset atrial fibrillation [28]. An association with atrial fibrillation, particularly recent onset atrial fibrillation, and cardioembolic stroke raises a number of intriguing possibilities. Uncomplicated atrial fibrillation is not generally associated with troponin leak. However, in the setting of rapid atrial fibrillation [113, 154] or cardiac failure precipitated by atrial fibrillation [170] troponin leak can occur. The association could be purely due to troponin elevation being linked to lesion size and stroke severity, as it is established that cardioembolic strokes are more severe [33]. One further potential connection is that atrial fibrillation may lead to simultaneous embolisation to the brain and coronary vasculature [119]. One detailed study of seemingly cryptogenic stroke in which cases with atrial fibrillation were excluded found an association between troponin elevation and evidence for a cardioembolic source on detailed echocardiography. This suggests that at least in some cases it may be the cardioembolic nature of the stroke that is the cause of troponin rise rather than the cardiac

consequences of any underlying pathology [174]. An association between new onset atrial fibrillation and lesions involving the insular cortex has also been described [60].

Conversely it is not inconceivable that acute stroke may result in atrial fibrillation. A variety of arrhythmias including atrial fibrillation have been described in acute stroke [123] and subarachnoid haemorrhage [54]. In this scenario the troponin rise and onset of atrial fibrillation might both be triggered by some common pathophysiological mechanism. However, as atrial fibrillation is pre-existent in the majority of cases of acute stroke with troponin rise this is unlikely to be a common mechanism.

Atrial fibrillation is known to contribute to a worse outcome in acute stroke [172] and is associated with an increased risk of cardiac complications [204]. This raises the possibility that the mechanisms for a worsening of outcome in acute stroke for both atrial fibrillation and troponin elevation may be the same or have some overlap. One likely mechanism in common is cardiac failure.

5.7.2. Takotsubo Cardiomyopathy

A reversible form of stress-induced cardiomyopathy has been described to occur in the setting of high emotional or physical distress [177]. This syndrome termed stress-induced cardiomyopathy or takotsubo cardiomyopathy (in reference to the similarity of left ventriculographic appearances to the shape of a Japanese octopus pot) leads to apical ballooning of the left ventricle in response to sympathetic overflow to the heart (Figure 10). The syndrome is more common in postmenopausal women and has an in-patient mortality of around 4% [27, 182]. If the acute phase is survived, the pathological changes appear to resolve completely with little or no long term effects. Pathological examination of cases of sudden death in similar stressful circumstances has demonstrated a particular sub-endocardial lesion, contraction-band necrosis (also known as myofibrillar degeneration) [17, 32]. A very similar pathology can be induced in animals with high levels of catecholamines and there is evidence to suggest that the trigger for these microscopic pathological changes is a massive influx of calcium into the myocytes triggered by reperfusion [226]. Similar findings have been described in animal models of subarachnoid haemorrhage [74]. However, this pathology is not seen in all cases of takotsubo cardiomyopathy and milder changes can be seen [220]. A key component of the diagnosis is the demonstration of normal coronary arteries [163].

A non-ischaemic multifocal transmural myocardial pattern of damage has been described in 13/25 (52%) of fatal cases with cerebral infarction and 9/13 (69%) with intracerebral haemorrhage [120]. Takotsubo cardiomyopathy has been described in association with both ischaemic and haemorrhagic stroke in single case reports [31, 114, 179, 184] and small series [73, 224]. In one series 6/7 patients had lesions involving the insular cortex [224]. Takotsubo cardiomyopathy is known to be associated with elevations in serum troponin [63], but this is not always seen. Generally, levels are somewhat intermediate between those seen in extensive myocardial infarction and normal levels. Takotsubo cardiomyopathy is also associated with elevations of NT-proBNP [153] and the levels are higher than in acute coronary syndromes [5]. Peak troponin levels are achieved on day 1 and NT-proBNP levels are seen to rise quite dramatically at day 2 [63].

The commonest ECG changes seen in takotsubo cardiomyopathy include T wave inversion, QTc prolongation, ST-segment elevation and Q waves [195]. This mirrors closely the pattern of ECG changes typically seen in both ischaemic [65] and haemorrhagic [85] stroke with troponin elevations.

Figure 10. Angiographic images showing (A) apical ballooning of the left ventricle in systole and (B) normal coronary arteries.

Several studies of troponin elevation in acute stroke have included echocardiography [13, 34, 45, 98]. It is noteworthy that none of these studies has specifically identified any cases of takotsubo cardiomyopathy. However, in two studies echocardiography was performed within 3 days of admission [45, 98] and for the other two no time criteria or data were given. It is known that the echocardiographic features of takotsubo cardiomyopathy can resolve within 48 hours [55, 167] and thus the typical appearances might be missed after this window. The ventricular morphology associated with takotsubo cardiomyopathy can be variable [96] with *formes frustes* of takotsubo cardiomyopathy also having been suspected [64].

The most commonly postulated pathogenesis for takotsubo cardiomyopathy is that an intensely stressful emotional or physical trigger causes an excess of circulating catecholamines which causes both direct myocardial toxicity as well as microvascular dysfunction, which leads to myocardial stunning and the consequent contractile dysfunction [219]. The more dense distribution of adrenoceptors at the apex is thought to explain why the apex is usually affected while the base of the ventricle is spared.

Perhaps the most striking argument against takotsubo cardiomyopathy being a significant contributor to troponin elevations in acute stroke is the demographic profile of those affected. Oestrogen is associated with attenuated catecholamine-mediated vasoconstriction [193]. Consequently oestrogen deficiency is thought to explain the higher incidence of takotsubo cardiomyopathy in post-menopausal women. Whilst stroke patients with troponin rise are certainly older, the gender distribution was the same as for those with normal troponin levels. However, the pathophysiology in the setting of stroke may be different and a partial form of takotsubo cardiomyopathy may be responsible.

As well as takotsubo cardiomyopathy arising as a consequence it is also possible that stroke can arise as a complication of this pathology which is associated with a risk of embolisation [139].

5.8. Stroke and the Autonomic Nervous System

In the human body, the most important catecholamines are adrenaline, noradrenaline and dopamine. Catecholamines are produced mainly by the chromaffin cells of the adrenal medulla and the postganglionic fibres of the sympathetic nervous system [129]. Release of these hormones from the adrenal medulla is part of the fight-or-flight response. Following release of the neurotransmitter noradrenaline (adrenaline from the sympathetic adrenergic nerves) it binds to specific adrenergic receptors in the target tissue to produce physiological response.

Vascular smooth muscle has a large number of α_1 receptors relative to β_2 receptors. However, adrenaline has a higher affinity for the β_2 receptors relative to the α_1 receptor [125]. Activation of the β_2 receptor would produce vasodilatation while activation of the α_1 receptor would result in vasoconstriction [4]. At low doses, adrenaline can selectively stimulate β_2 receptors. However, as the concentration of adrenaline increases, the predominant effect is vasoconstriction. Noradrenaline in physiologically relevant concentrations has little affinity for β_2 receptors. It stimulates α_1 receptors producing vasoconstriction.

Normally, small coronary arteries and arterioles are the principal determinants of coronary vascular resistance [39]. Their calibre is determined by the resting tone of the autonomic nervous system [40]. Responses to α -adrenoceptor activation are augmented in the presence of coronary endothelial dysfunction and atherosclerosis, involving both α_1 - and α_2 -adrenoceptors in epicardial conduit arteries and microvessels. Such augmented α -adrenergic coronary constriction is powerful enough to induce myocardial ischemia and limit myocardial function [87]. Both α_1 - and α_2 -adrenoceptors mediate coronary vasoconstriction with α_1 -adrenoceptors more predominant in larger vessels and α_2 -adrenoceptors more predominant in the microcirculation [38]. The overall effect of sympathetic stimulation on the cardiovascular system is to increase heart rate and blood pressure (Figure 11).

The central pathway of cardiac control involves what has been termed the cardunculus in the insular cortex via central connections through the hypothalamus and ultimately outflow tracts through the vagus nerve to the heart [157, 165]. Both sympathetic and parasympathetic drive to the heart may be governed by the insulae via the hypothalamus. An MRI study identified the insular region as being more commonly involved in stroke patients with right cerebral artery territory infarction and elevated troponin level [21]. However, another study failed to find any association between lesions of the insular region and elevations of troponin or ECG changes [41]. This study also provided additional evidence for a significant stress response in acute stroke, in the form of elevations in cortisol and TNF- α levels. In stroke, insular infarction, night-time blood pressure increase and increased serum noradrenaline concentrations are independent risk factors for unfavourable functional outcome (measured by the Barthel index) at one year of follow-up [171], and it has been hypothesised that persistent autonomic activation is related to poor functional outcomes because of the cardiovascular sequelae [171, 200]. An association between acute stroke, elevated noradrenaline levels, CK levels and arrhythmias has been demonstrated [145]. More recently, asymmetric right midbrain activation has been shown during mental and physical stress induced pro-arrhythmic ECG abnormalities [44].

Figure 11. Illustration of the principal cardiovascular efferents of the autonomic nervous system.

An excess of catecholamines and associated myocardial injury have been demonstrated in an animal model of MCA territory infarction [79] and a specific association with lesions of the insular cortex has also been described in an animal model [185]. Elevated catecholamine levels have also been demonstrated in acute stroke patients [146] and elevations do not appear

to correlate well with lesion volume or stroke severity [146, 160]. Various degrees of AV block and tachyarrhythmias have been induced in animals through stimulation of the cingulate gyrus [186], amygdala [166], posterior thalamus [141] and vagus nerve [50].

The importance of the vagus nerve has been demonstrated, particularly for sinus nodal function [165]. Experiments by Oppenheimer demonstrated that the central pathway of cardiac control involves the hypothalamus and the insular cortex [158]. Stimulation of the parasympathetic nervous system has also been demonstrated to induce myocardial ischaemia in animals [75].

It has been noted that the sinoatrial and atrioventricular nodes have predominantly parasympathetic innervation, whereas sympathetic innervation predominates in the ventricular muscle [37]. Stimulation studies in humans undergoing epilepsy surgery have indicated a predominantly sympathetic output from the right insula and parasympathetic output from the left insula [157]. This finding has been supported by studies in psychological paradigms [218] and migraineurs [19]. A specific association between stroke affecting the right insular cortex and an increased risk of heart rate variability and sudden death has been reported [200]. Previous studies have found that patients with right hemispheric infarcts, compared to those with left sided infarcts, have a significant increase in supraventricular arrhythmias [43, 126]. The hypothesis that right hemisphere strokes produce an impairment in the parasympathetic mediated heart rate response with a reciprocal rise in sympathetic tone, making supraventricular tachycardias more likely has been proposed. The data presented in this chapter would not suggest a similar differential lateralisation effect for insular involvement with regards to troponin elevation in acute stroke and the data in the published literature relating to this are complex [156].

The principal afferents for cardiovascular autonomic control are the baroreceptors of the carotid sinus and the chemoreceptors of the carotid body which pass via the glossopharyngeal nerve, petrosal ganglion and the nucleus of the tractus solitarius to synapse with motor nuclei in the medulla and central control centres, including the hypothalamus [46]. Afferents from the aorta and heart also travel with the vagus nerve. There are additional baroreceptors and chemoreceptors in the area postrema and the hypothalamus which directly influence autonomic outflows [78, 143, 189].

5.9. Mechanistic Summary

A summary of probable mechanisms for troponin leak in acute stroke is given in the form of a Venn diagram with associated risk factors in Figure 12. The available evidence points to pre-existent or co-occurring cardiac conditions accounting for perhaps half of elevations in troponin levels in acute stroke with the remainder arising as sympathetic overflow syndrome characterised by left ventricular dysfunction, ECG changes (which may appear ischaemic) and arrhythmias. In some instances this picture may include frank infarction or a takotsubo cardiomyopathy syndrome but in most cases the cardiac sequelae are less obvious but are still associated with a poorer prognosis. The fact that very similar cardiac features are seen in subarachnoid haemorrhage [176] and raised intracranial pressure [120] points to a more generic stress response rather than a lesion location specific response. In subarachnoid haemorrhage there is also a very clear relationship between the severity of neurological insult and troponin levels [205].

6. TREATMENT IMPLICATIONS

Patients with stroke and troponin elevation should be managed on a case by case basis. In selected cases with chest pain or associated dynamic ECG changes inpatient angiography should be considered. In the majority of patients invasive investigations can be avoided and management of the troponin leak should be conservative. Echocardiography may play an important role in identifying regional or global wall motion abnormalities, intracardiac thrombus, vegetations and aortic dissection. Echocardiography could also be helpful in detecting stress induced cardiomyopathy with apical ballooning following stroke.

IHD = ischaemic heart disease; RF = renal failure; AF = atrial fibrillation; CHF = congestive heart failure.

Figure 12. Venn diagram illustrating aetiology of troponin rise in acute stroke.

The notion of a sympathetic overflow syndrome complicating stroke has led to the concept of using β -blockers or calcium channel antagonists in acute stroke to ameliorate these effects. Animal models of these treatments given prior to the induction of cerebral infarction have proven to be of some benefit [10, 95, 111]. However, trials of β -blockers in humans for unselected patients with acute stroke have shown no benefit and may have had some harmful effect [23]. Similarly studies of calcium channel antagonists have been disappointing in

humans [90, 91]. This may be because of other effects on atrioventricular conduction or blood pressure, or simply because late administration is ineffective. Studies of their value in takotsubo cardiomyopathy have been similarly disappointing [59] and it may well be that once the sympathetic overflow has occurred and contraction band necrosis is present in myocytes that treatment of this sort is ineffective. Pre-admission β -blockers have been found to be effective in preventing stunned myocardium in subarachnoid haemorrhage [128].

Angiotensin converting enzyme inhibitors which are of proven efficacy in cardiac failure [103] are on the other hand also of known benefit in the setting of stroke [76]. The benefit of angiotensin converting enzyme inhibitors is not limited to secondary prevention they also reduce short term morbidity before any significant effects on blood pressure will have been seen [15]. Thus whilst originally introduced for their secondary preventive effects on blood pressure in stroke, it may be their effects on cardiac failure that are also a significant reason for their efficacy in the short term. There is emerging evidence that the acute control of hypertension in the case of intracerebral haemorrhage may be safe and beneficial [9, 12], but further definitive studies are awaited.

Administration of atropine prevented myocardial injury in an animal model of parasympathetic induced myocardial ischaemia [75]. Knowledge regarding the relative contributions of the sympathetic and parasympathetic components of the autonomic nervous system in acute stroke may be required in order to more specifically target any proposed acute treatments.

CONCLUSION

Troponin rise following stroke is seen in a modest but significant proportion of patients with acute stroke. The frequency is around 10% in ischaemic stroke and 18% in haemorrhagic stroke. There is a clear association between troponin rise and the size of cerebral lesion as well as atrial fibrillation and a cardioembolic aetiology. It seems likely that these factors are intertwined, and that it is the greater severity of stroke seen with intracerebral haemorrhage and embolic infarcts that is the principal driver of these associations. Myocardial infarction is the cause of troponin rise in acute stroke in a minority of cases (10%) and the common pathway for troponin elevation in the remainder appears to be cardiac stress or failure: either pre-existent; precipitated by atrial fibrillation; or more commonly a cerebrally induced autonomic disturbance. Whether this is psychologically induced or due to a disturbance of central control remains to be established but the frequency of frank takotsubo cardiomyopathy as a cause appears to be low, but the results of further studies is eagerly awaited.

Troponin elevation is an independent predictor of a poor outcome following stroke both in terms of mortality and morbidity, but its clinical usefulness in this setting has been questioned [212]. The sensitivity at standard cut-off levels for troponin is low but the specificity for the outcome of death is high making this a potentially useful predictive test. Simple clinical measures such as the NIHSS or SSS have similar or better specificity and much higher sensitivity in predicting an adverse outcome and purely clinical tools for predicting outcome in stroke appear to be very adequate [175]. At the present time the influence of finding an elevated troponin in stroke is limited in terms of treatment, but as a marker of cardiac failure and cardioembolic aetiology this test may assist in directing

appropriate investigations. Current stroke management guidelines in Australia [150] and the United Kingdom [149] do not recommend routine troponin measurement in acute stroke but guidelines from the American Stroke Association do [2]. Simply as a screen for acute coronary syndrome is probably justification enough for the routine measurement of troponin levels in acute stroke.

Further research is required to elucidate the nature of the relationship between the identified risk factors for troponin elevation in acute stroke and the mechanisms for this. A formal meta-analysis of raw data from available studies using regression analysis approaches would be a useful starting point for generating hypotheses. A prospective observational cohort study collecting, demographic, vascular risk factor, serological, imaging, ECG, echocardiographic, neurosonological and Holter monitor data in a large group of patients with acute stroke, together with coronary angiography in a subset has been proposed [122]. Another prospective observational study using formal angiography in appropriately selected patients (TRELAS) [178] will certainly be of value in answering some of the remaining questions. Key elements of any such studies would be to include all cases of stroke (haemorrhagic and ischaemic), inclusion of troponin, NT-proBNP, CK and catecholamine levels as part of the serological testing, repeated serological and ECG testing to give a dynamic picture of the myocardial injury [104], measures of stroke severity, lesion volume and assessment of cardiac function with echocardiography or angiography. A defined outcome measure such as modified Rankin scale score at 90 days would also be important. Whilst formal angiographic studies are problematic in the acute stroke setting and may even be contraindicated, improvements in computed tomography [223] and magnetic resonance [116] coronary angiography offer intriguing non-invasive alternatives. The issue of whether or not involvement of the insular cortex in stroke is associated with a greater risk of cardiac sequelae also requires resolution. Detailed lesion analysis could shed light on the central control of cardiac autonomic functioning.

We suspect that cardiologists, neurologists and philosophers alike will continue to argue over whether it is the heart that rules the mind or the mind that rules the heart, but what is clear in the case of troponin elevations in stroke is that, as in real life, the truth is always much more complicated and the two are very much interdependent.

Chapter 63

HOW COULD FLUOXETINE EXERT THERAPEUTIC EFFECTS IN STROKE?

Virginie Beray-Berthet, Michel Plotkine and Raymond Mongeau*

Pharmacologie de la circulation cérébrale EA4475, Université Paris Descartes, Paris

ABSTRACT

Stroke is among the leading causes of morbidity and mortality worldwide. The current pharmacological treatment of stroke is early reperfusion and fibrinolysis of the ischemic brain area using the recombinant tissue plasminogen activator (rt-PA, alteplase). Much effort has been invested into the discovery of other pharmacological therapies to provide neuroprotection and to reduce the late neurological and psychiatric deficits associated with stroke. Among the numerous strategies proposed, there is the administration of antidepressant drugs. The recent report that the selective serotonin reuptake inhibitor (SSRI) fluoxetine provides neuroprotection and can improve motor deficits in patients is particularly encouraging. In addition to its well-known therapeutic effect in depression, a frequent long-term consequence of stroke, fluoxetine might exert additional effects after cerebral ischemia independently of its antidepressant effect *per se*. The present review examines various short and long-term mechanisms through which fluoxetine and other SSRIs might exert their therapeutic effects in stroke. In addition to the facilitation of serotonergic transmission, *via* long term regulations of 5-HT receptor functions and neuroplasticity, SSRIs could have important beneficial effects on haemostasis, vasomotricity, trophic and inflammation factors (BDNF, cytokines, microglia, ...) that can reduce the initial consequences (infarct size, sensorimotor deficits) as well as the long term emotional deficits of stroke.

Keywords: Antidepressant drugs; Blood brain barrier; Cerebral ischemia; Cerebral blood flow; Haemostasis; Inflammation; Neurogenesis; Neuroprotection; Neurovascular unit; Post-stroke depression; Trophic factors

1. INTRODUCTION

Fluoxetine and other selective serotonin reuptake inhibitors (SSRIs) are first line treatments for depression and anxiety. Furthermore, SSRIs are also effective treatments for the long-term emotional deficits associated with stroke, namely post-stroke depression, and could possibly be effective also for the long term cognitive deficits associated with this disease since, as in depression, these might be associated with chronically low extracellular 5-HT levels (Cowen & Sherwood, 2013; Jorge et al., 2010). However, prior to cognitive and depressive symptoms, stroke is mostly recognized by sensory-motor deficits. Cholet et al. FLAME multicenter study about the beneficial effect of fluoxetine for stroke recovery, in particular for motor functions, had recently a considerable impact (Chollet et al., 2011; Cramer, 2011). Indeed, patients that had suffered stroke of moderate severity, but with severe arm and leg motor weakness, treated few days after with fluoxetine experienced great neurological benefits independently of the therapeutic effect of fluoxetine on depressive symptoms. As indicated by functional magnetic imaging, these effects on motor performances are reflected by activity changes at the level of the motor cortex (Pariente et al., 2001). Since then, systematic reviews and meta-analyses have shown the efficacy of SSRIs in reducing dependency and disabilities associated with stroke (Mead et al., 2012), in agreement with older studies suggesting that antidepressant drugs (ADs), and in particular those acting on the serotonergic system, reduce the neurological disabilities occurring after stroke (Cramer, 2011; Mead et al., 2012).

Because fluoxetine might eventually become a first line treatment for stroke neurological symptoms, our goal here was to review, at physiological, cellular and behavioral levels, how SSRIs could exert therapeutic effects on the various facets of stroke.

Stroke is defined by the interruption of blood perfusion to a part of the brain. This cuts off the oxygen and nutrients supplies, and thereby causes damages to brain tissues. The majority of strokes is ischemic (85% are due to the occlusion of a blood vessel by a thrombus or an embolus), while a minority of them is hemorrhagic. Stroke is a serious neurological disease, particularly common and disabling. It affects 22 million people worldwide each year, and this number is increasing because of the aging population (IST-3 collaborative group et al., 2012). It is the second cause of death worldwide after cardiovascular diseases, being responsible for 9.7% of deaths in 2004 and this is expected to reach 12.1% in 2030 (Mathers et al., 2009). In addition, stroke is the leading cause of acquired disability in adults and is the second cause of dementia after Alzheimer's disease (Acheampong & Ford, 2012). Stroke diagnosis needs to be done as early as possible to limit its consequences and implement an appropriate treatment. The phrase "time is brain" emphasizes that nervous tissue is rapidly lost as a stroke progresses, since a typical patient loses 1.9 million neurons each minute stroke is untreated (Saver, 2006). Sudden neurological symptoms rapidly progressing over a few minutes or a few hours may be signs of a stroke. The most common stroke symptoms include hemiparesis that may involve face, arm and leg, hemisensory disturbances, gaze deviation, language disorder (dysphasia) and visuospatial neglect.

Risk factors for ischemic stroke include age, the most powerful factor (the risk of stroke doubles every decade after 55 years), gender (prevalence is higher in men), ethnic background, and family history. Modifiable risk factors are represented by hypertension, which is the major risk factor, heart diseases (atrial fibrillation being the most important),

smoking, diabetes and hyperlipidemia. Other possible modifiable risk factors are obesity, diet, physical activity, alcohol consumption, contraception, and hormone replacement therapy (Goldstein et al., 2011). Among psychological risk factors, a depressive mood may predispose to a stroke, in particular an ischemic stroke (May et al., 2002; Ohira et al., 2013). Metabolic changes characteristic of depressive patients may underlie this increased propensity for stroke. Depressed individuals very often have increased autonomic sympathetic activity that may lead to increased platelet activity. Furthermore, a hallmark of depression is the excessive secretion of glucocorticoids that itself promotes conventional stroke risk factors, such as hypertension. Elevated glucocorticoids are also known to decrease neurogenesis and trophic factors, which as we will see in section 3.2, may be stroke recovery mechanisms. Interestingly, depression and anxiety are associated with exaggerated serotonin-mediated platelet activation (Zafar et al., 2010), but patients treated with SSRIs may be protected against this risk factor, as 5-HT uptake inhibition have an inhibitory effect on platelet activation by decreasing 5-HT content inside platelets and thereby reducing platelet plug formation (Geiser et al., 2011; Hergovich et al., 2000).

Beyond a risk factor, depression is also known as a main consequence of stroke. The psychological distress reactions generated by the stroke itself may explain this late emotional deficit (Gainotti et al., 1997). Nevertheless, many authors insist instead on biological causes. Depression occurs more often in the stroke population than in patients presenting similar levels of disability from other diseases (Folstein et al., 1977). Post-stroke depression could be the result of a brain lesion in a region regulating emotions such as the prefrontal cortex (Terroni et al., 2011). However, whether an augmented risk of depression does exist after a stroke in a specific brain location rather than another remains a matter of debate (Carson et al., 2000; Narushima et al., 2003). In any case, lesions in areas such as the prefrontal cortex should have an important impact through their projections on monoaminergic systems. These systems and the neural circuits regulating mood and anxiety might suffer from a generalized damage to the brain vasculature, as first claimed in the “vascular hypothesis” of depression (Taylor et al., 2013). In contrast to post-stroke depression, which involves an acute and focal lesion, vascular depression would be the consequence of chronic small ischemic lesions to frontal and subcortical circuits regulating emotion and cognition. It is particularly fitted to explain late-onset depressions occurring after age 50. In old depressed patients who have experienced a brutal mood transformation, symptoms are more likely accounted by a biological dysfunction than traits and personality. Imaging studies have revealed abnormally of the white matter (white matter hyperintensities) in several brain areas of depressed patients, including the prefrontal cortex (Tupler et al., 2002). These small infarcts largely asymptomatic at first could eventually trigger a major depression, dementia or the occurrence of a larger ischemic stroke, itself leading to post-stroke depression. Note that fluoxetine and other SSRIs are well-tolerated first line agents to treat late-life depression, whether or not associated with stroke (Solai et al., 2001).

We will argue in the present review that fluoxetine is a pleiotropic drug for stroke treatment. Putative mechanisms explaining the beneficial effects of fluoxetine are multiple and may explain as much the therapeutic effects on motor functions as those on mood and cognition. First, SSRIs are known to have neurotrophic effects by acting on the production of growth factors, such as the brain derived nerve growth factor (BDNF) and other processes such as hippocampal neurogenesis. Migration of new neurons to damaged brain areas have been shown to occur after stroke (Wiltout et al., 2007). Both neurogenesis and angiogenesis

in stroke areas appear to be facilitated by SSRI treatments (Espinera et al., 2013). Second, SSRIs may have neuroprotective effects by reducing inflammation *via* an action on cytokines and by repressing microglia activation, and third, they might be acting on vascular and haemostasis parameters immediately after stroke (Geiser et al., 2011; Ofek et al., 2012). Finally, on the psychological sphere, the antidepressant and anxiolytic effects of chronic SSRI may help stroke recovery by attenuating a cascade of distress related processes.

1.1 The Neurovascular Unit and the Cerebral Blood Flow

To better understand brain damages caused by stroke, we need to consider primary events taking place at the blood brain barrier (BBB). The BBB regulates the entry of nutrients and drugs into the brain from circulating blood. As shown on figure 1, the BBB is composed of endothelial cells, a basement membrane, pericytes and astrocytic feet. All these elements are necessary to control exchanges between the blood and the brain parenchyma. Together with neurons and glial cells, they form a functional unit called the neurovascular unit.

Changes in the integrity of the BBB are central to the pathophysiology of cerebral ischemia. Ischemic stroke can disrupt the neurovascular unit at both the structural and functional levels, which leads to abnormal leaks across the BBB. Models of cerebral ischemia revealed how expression of both inter-endothelial junction proteins (such as occludin) and components of the basal membrane (such as collagen IV and laminin) can be decreased. Swelling of astrocytes leads to the detachment of their microvascular endfeet (figure 1). Among the mechanisms underlying post-ischemic damage of the BBB, those involving metalloproteinases (MMPs) play a major role by degrading the extracellular matrix and interendothelial junctions. These proteolytic enzymes expressed by endothelial cells, microglial cells, neurons, astrocytes and infiltrating inflammatory cells are involved in brain remodeling after cerebral ischemia (section 1.4).

Fluoxetine may inhibit ischemia-induced cell death and cognitive impairment, by preventing BBB disruption indirectly *via* its action on astrocyte / microglial activation and inflammation (Lee et al., 2014). It may also possibly act directly at the level of the neurovascular unit itself because expression of the 5-HT transporter (5-HTT) mRNA has been detected in cultured immortalized rat cerebral endothelial cell lines (Brust et al., 2000). This transporter appears to be localized on both the luminal and the abluminal sides of brain capillaries (figure 1; Wakayama et al., 2002).

Following an ischemic insult, there is a persistent microvascular constriction that results in part from pericyte contraction (Liu et al., 2012; figure 1). Post-stroke vasospasms and BBB dysfunctions also involve blood vessels composed of vascular smooth muscles regulating cerebral blood flow through innervation from noradrenergic, GABAergic, cholinergic and serotonergic neurons (Hawkins & Davis, 2005). Both *in vitro* and *in vivo* studies have shown that 5-HT act not only as a synaptic neurotransmitter in the central nervous system, but also as a potent vasoactive agent of the brain vasculature. 5-HT nerve fibers have been observed through the use of an antibody to tryptophan hydroxylase (the 5-HT synthesis enzyme), in major cerebral arteries and small pial vessels. These projections appear to be either of central origin, from the rostral raphe nucleus, or of peripheral origin, from the superior cervical ganglion (Bonvento et al., 1991). Because of its localization in key vascular targets, 5-HT is thought to play a pivotal role in coupling cerebral blood flow to metabolism. It decreases

oxygen and glucose consumption, depresses electrical activity in the cortex and reduces cerebral blood flow, mainly when the BBB is disrupted (for a review see Bonvento et al., 1991). Heterogeneous post-synaptic receptors (5-HT₁, 5-HT₂, 5-HT₇, ...) are involved in the vasomotor effects of 5-HT depending on the species, anatomically distinct vessels and even different segments of the same vessel (Bonvento et al., 1991). Some of the vasoconstrictor effects of 5-HT in small cerebral arteries are mediated by 5-HT_{2A} receptors via voltage-dependent Ca²⁺ channels (Ungvari et al., 1999). Furthermore, activation of 5-HT₃ receptors on GABAergic interneurons can indirectly mediate either constriction or vasodilatation via neuropeptide Y or NO, respectively (Perrenoud et al., 2012). Finally, the inhibitory somatodendritic 5-HT_{1A} autoreceptors on 5-HT neurons of the raphe nuclei could also play a role in increasing cerebral blood flow (Bonvento et al., 1997; Marco et al., 1999). Activation of inhibitory autoreceptors, as occurring when extracellular 5-HT concentration is increased by an SSRI, may thus decrease the postsynaptic receptor-mediated vasoconstrictor effect of 5-HT.

Figure 1. The principal elements constituting the neurovascular unit.

Endothelial cells form a continuous layer at the luminal surface of the capillary. They limit the permeability of the barrier via four defense levels: 1) interendothelial tight and adherens junctions that greatly reduce the paracellular flux through various proteins such as the tight junction protein occludin, 2) few pinocytotic vesicles forming a transcellular barrier, 3) enzymatic barriers and 4) endothelial cells expressing a large number of efflux transporters that allow efflux of toxins and drugs. Some of them participate to a certain extent to the inactivation of several neurotransmitters, including glutamate, GABA, noradrenaline and, in particular, 5-HT via the 5-HTT localized on both the luminal and abluminal sides. It is noteworthy that endothelial cells also express endothelial NO synthase (eNOS) exerting endothelium-dependent vasodilatation, platelet aggregation inhibition and anti-oxidant effects contrasting with the deleterious action of the inducible NOS (iNOS) triggered during inflammation. *The basal membrane* is an extracellular matrix on which is based the cerebral endothelium. It is composed of various proteins such as the cell adhesion molecule laminin and collagen IV. *Astrocytes* form a link between the endothelium and neurons. The astrocytic endfeet cover over 99% of the surface on the basement membrane of capillaries and microvessels. *Microglial cells* are also found in the perivascular space. They play a very important immunological role since they are the resident macrophages of brain

tissue. *Pericytes* are poorly differentiated contractile cells spreading around the capillary wall. Drowned in the basement membrane, pericytes cover the endothelium and provide structural support to blood vessels. Pericytes regulate brain capillary blood flow through contraction and relaxation (the figure was modified from Abbott et al., 2010).

1.2 Stroke and Cerebral Ischemia

Haemostasis, that prevents blood loss when vessels are damaged, is a vital defense process. It involves activation and adhesion of platelets, and subsequently fibrin matrix and blood clot formations. It can pathologically occur, however, in absence of bleeding, such as in stroke. The majority of strokes are ischemic, that is - due to the occlusion of a blood vessel by a thrombus or an embolus. A « haemostatic » plug interrupts blood flow, thereby causing cerebral ischemia and death of brain tissue downstream (infarction). In focal ischemia, occlusion of a cerebral artery occurs after migration of an embolus of extracerebral origin or by the formation of a thrombus *in situ*. The latter emerges in reaction to atherosclerosis or other vascular dysfunctions. The most frequently occluded cerebral artery is the middle cerebral artery (MCA). Ischemic areas are divided into the core area, where the fall in cerebral blood flow is severe enough to causes irreversible tissue loss (i.e., cell death), and the penumbra, which has residual blood flow and consists of cells initially not showing alterations of morphological integrity, but having impaired functions. The latter cells remain alive for a few hours and are the target of neuroprotective and reperfusion treatments.

Most of the preclinical studies on cerebral ischemia, in particular those about the effects of SSRIs (section 2 and 3), derive from animal models of cerebral ischemia that reproduce focal ischemia. They consist in MCA occlusion (MCAo), for instance by a microclip or by introducing a nylon filament to block blood flow. In other models, occlusion is carried out by injecting blood clots or thrombin into the artery. *In vitro* models are performed on cell cultures, more rarely on cultured brain slices. Different cell types can be cultured (neurons, astrocytes, oligodendrocytes, microglia, endothelial cells; see figure 1) alone or in co-cultures, such as astrocytes / neurons co-cultures. Cells are exposed to deprivation of either oxygen or glucose reproducing *in vitro* ischemic conditions. They can also be subjected to conditions that mimic some other events of cerebral ischemia: oxidative stress or glutamate-induced excitotoxic stress. These studies revealed the important consequences of ischemia on brain cells, as detailed in the following section.

1.3 Cellular Consequences of Brain Ischemia: Glutamate-Induced Excitotoxicity, Oxidative Stress and Inflammation

Following cerebral ischemia, the decrease in cerebral blood flow reduces input of energy substrates, oxygen and glucose. Energy depletion notably disrupts the function of the Na^+/K^+ ATPase, which consumes under physiological conditions, 70% of the brain energy resources. The resulting loss of ionic gradients triggers neuronal depolarization and increases the release of neurotransmitters, particularly the main excitatory amino acid glutamate. This leads to an accumulation of glutamate into the extracellular medium and excessive stimulation of its receptors, including the NMDA (N-methyl-D-aspartate) receptor. These receptors operating

channels, widespread in the central nervous system, are permeable to Ca^{2+} . The glutamate-mediated increase in intracellular Ca^{2+} concentration stimulates proteases, lipases, endonucleases, and neuronal NO synthase (nNOS), all contributing to the so-called excitotoxic cell death (Doyle et al., 2008; Turner et al., 2013).

In parallel with the huge increase in glutamate extracellular concentration, there is also a dramatic increase in 5-HT levels associated with brain ischemia (Kanthan et al., 1996; Nagao et al., 1995). Similarly to glutamate, 5-HT is associated with the negative consequences of brain injuries, such as brain edema formation and BBB disruption, because these consequences are attenuated by either 5-HT biosynthesis inhibition or 5-HT antibodies (Sharma et al., 2007). Furthermore, following BBB disruption, increasing 5-HT levels produces marked decreases in blood perfusion in numerous brain areas (Grome & Harper, 1983). Acute 5-HT reuptake inhibition with citalopram was shown to reduce ischemia-induced 5-HT hypermetabolism (Nagao et al., 1995).

Under physiological conditions, cells produce various free radicals, in particular through their mitochondrial respiratory chain. There is normally a dynamic equilibrium between the formation of free radicals and their disposal by endogenous enzymatic antioxidant systems (superoxide dismutase, glutathione peroxidase) and non-enzymatic processes (glutathione, vitamin E, vitamin C, ...). After brain ischemia, mitochondrial respiratory chain dysfunction and post-ischemic activation of various enzymes, such as iNOS and COX, leads to overproduction of free radicals, especially reactive oxygen species (ROS) including superoxide anion ($\text{O}_2^{\cdot-}$), hydroxyl radical ($\cdot\text{OH}$) and nitric oxide ($\cdot\text{NO}$). Under ischemic conditions, depletion of the L-arginine substrate and/or the co-factor BH₄, required for coupling two functional eNOS subunits, generates excessive ROS in endothelial cells leading to eNOS uncoupling. In an uncoupled state, eNOS produces harmful $\text{O}_2^{\cdot-}$ instead of the beneficial endothelial NO (which exerts vasodilation and antithrombotic effects). Once generated, $\text{O}_2^{\cdot-}$ activates several stress-sensitive pathways and scavenges NO to produce ONOO⁻, a highly reactive pro-oxidant that elicits direct neurotoxic effects (Srivastava et al., 2012). This ONOO⁻ causes DNA damages that hyperactivate the poly(ADP-ribose)polymerase (PARP), a DNA repair enzyme known to be deleterious when it is over activated during cerebral ischemia (Haddad et al., 2006; Szabó & Dawson, 1998). Post-ischemic overproduction of ROS also exceeds the capacity of endogenous antioxidant systems causing membrane lipid peroxidation, protein oxidation and cell death (Pradeep et al., 2012).

Post-ischemic oxidative stress and the resulting necrotic cells trigger the production of inflammatory cytokines. These initial events lead to the activation of microglial cells that in turn, produce glutamate, cytokines and chemokines in large amounts, which themselves causes the expression of adhesion molecules by endothelial cells. This triggers the adhesion of circulating inflammatory cells, *i.e.* leukocytes (neutrophils, lymphocytes and monocytes) to the endothelium and their subsequent infiltration into the brain parenchyma. Infiltrated leukocytes and microglial cells express and release various inflammatory mediators (cytokines, MMPs, iNOS, ...; Ronaldson & Davis, 2012). High levels of neurotoxic mediators, such as high concentration of NO and peroxide, inflammatory cytokines and proteases are involved in the post-ischemic disruption of the BBB (Yenari et al., 2006). We will see that fluoxetine could target many of these damaging processes (see section 2.3).

1.4 Brain Remodeling after Cerebral Ischemia

Post-ischemic disruption of the BBB notably results from a rise in MMPs, proteolytic enzymes that have the ability to remodel the extracellular matrix. These enzymes are necessary for inflammation and wound repair by cleaving several substrates including growth factors, cytokines, cell surface receptors and cell adhesion molecules. Studies have demonstrated the induction of several MMPs (MMP-2,-3,-7,-9) following cerebral ischemia (Jin et al., 2010; Sandoval & Witt, 2008). Post-ischemic oxidative stress is implicated since MMPs can be strongly activated by free radicals. MMPs are secreted by astrocytes, endothelial, microglial and neuronal cells, and by neutrophils infiltrated in the damaged brain parenchyma (Lakhan et al., 2009).

MMPs can also cleave and activate proneurotrophins, leading to mature forms of growth factors such as BDNF, regulating neuronal survival and synaptic plasticity *via* its tyrosine kinase (TrkB) receptor (Hwang et al., 2005; Lee et al., 2001). BDNF levels are increased at and around the lesion site of an ischemic stroke, through a timely secretion from neuronal and non-neuronal sources (endothelial cells, astrocytes and microglia; Béjot et al., 2011). Together with growth factors secretion, stroke induces brain repair mechanisms by stimulating new neuronal formation. Neurogenesis is triggered by neural stem cells in the dentate subgranular zone of the hippocampus and the subventricular zone lining ventricles adjacent to this area. New neurons migrate within the hippocampus and other areas of the brain such as the striatum, and this migration occurs in close apposition to blood vessels. The vasculature thus plays an essential role in this migration since neurogenesis was shown to occur in parallel with hypoxia-induced angiogenesis (Thored et al., 2007). Furthermore, in addition to growth factors (such as BDNF), various mediators of the ischaemic-hypoxic response (erythropoietin) as well as glutamate intervene at different steps to regulate neural progenitor proliferation, migration and survival in the post-ischemic brain (Kokaia & Lindvall, 2003; Wiltout et al., 2007). This cell proliferation appears important since irradiation-induced ablation of neurogenesis exacerbates behavioral deficits after cerebral ischemia (Raber et al., 2004). Enhancement of serotonergic transmission by chronic fluoxetine might also boost brain remodeling after stroke as it stimulates BDNF secretion and neurogenesis (see section 2.4).

2. EXPERIMENTAL AND CLINICAL STROKE THERAPEUTIC AND THE ACUTE EFFECTS OF FLUOXETINE

2.1 Drugs Acting on Haemostasis

Thrombolysis with the recombinant tissue plasminogen activator (rt-PA, alteplase) remains the only pharmacological treatment currently available for acute ischemic stroke. Endogenous tPA converts inactive plasminogen to plasmin, which in turn degrades the fibrin matrix. Treatment with rt-PA thus aims to lyse the thrombus to allow recanalization of clotted artery, and thereby permits tissue reperfusion. Rt-PA is the only thrombolytic agent proved clinically effective when administered 4.30 hours after symptoms onset. However, to date, only 3-4% of patients suffering from an acute ischemic stroke are treated with intravenous rt-

PA. The barriers to thrombolysis are the delay in recognizing stroke symptoms at hospital arrival and the multiple contraindications to rt-PA administration. The use of rt-PA is indeed not without risk since it has been shown to enhance the occurrence of symptomatic hemorrhagic transformations *via* multiple factors, including inflammation (Haddad et al., 2013). Furthermore, early reperfusion after intravenous rt-PA can effectively be established in fewer than 40% of treated stroke patients (von Kummer & Hacke, 1992).

Interestingly, one possible mechanism through which fluoxetine exerts a beneficial action in stroke recovery is *via* an action on blood coagulation and fibrinolysis. 5-HTT plays a role in the activity of platelets: these anucleated cells are unable to synthesize 5-HT, but they actively uptake it from the plasma via 5-HTT. Endothelium damage, caused among other by arteriosclerosis triggers platelet activation and the content of platelet granules, including 5-HT, is released thereby enhancing the Ca^{2+} -dependent amplification of platelet activation. Although 5-HT *per se* does not activate platelets, it enhances platelet activation by factors such as ADP, adrenaline and thrombin via 5-HT_{2A} receptors (Li et al., 1997). Note that the latter receptors are also expressed on the vascular walls to exert, concomitantly with haemostasis, vasoconstriction (section 1.1). Interestingly, anxious and depressed patients treated with serotonergic ADs displayed enhanced fibrinolysis; these drugs thus prevent a basal state of enhanced blood coagulation produced by platelets hyperactivity in these patients (Geiser et al., 2011). Furthermore, 5-HT appears to have a crucial role in the formation of a subpopulation of platelets, the coated-platelets dually activated by collagen and thrombin, which may lead to a robust pro-thrombotic state, and accordingly, individuals treated with SSRIs have a reduced proportion of these platelets (Prodan et al., 2007). By blocking uptake and storage of 5-HT into platelets via 5-HTT, fluoxetine may prevent the platelet aggregation and coagulation cascade. Clinical studies that have investigated the existence of an association between chronic SSRI treatments and stroke did not detect, however, a reduced risk (de Abajo, 2011). Nevertheless, it is conceivable that acute fluoxetine administration after a stroke prevents reocclusion contributing to chronic small ischemic lesions. However, similarly to rt-PA, SSRIs might also increase the risk of brain hemorrhage, although this risk appears to be moderate (Hackam & Mrkobra, 2012).

2.2 Drugs Promoting Vasodilation and Blood Reperfusion

Recanalization with rt-PA is necessary, albeit not sufficient to allow full blood reperfusion of brain tissue via microvessels. Reperfusion is, in fact, a better predictor of stroke recovery than recanalization (Soares et al., 2010). Following cerebral ischemia, calcium not only triggers several deleterious enzymatic cascades (section 1.3), but also induces vasomotor contraction through voltage dependent-gated channels on microvessels smooth muscles, leading to vasospasms (Cipolla et al., 2014). Based on preclinical studies, the vasodilation effect of calcium antagonists, combined with their neuroprotectant action *via* an attenuation of intracellular Ca^{2+} concentrations, was hypothesized to confer therapeutic efficacy. Unfortunately, calcium antagonists, such as nimodipine, failed to show clinical benefits in several trials on ischemic stroke patients (Zhang et al., 2012).

Other drugs might be more suitable to release the vasospasms. Interestingly, fluoxetine might be such an agent because its acute administration was shown to produce vasodilation of cerebral arterioles and to ameliorate reperfusion of the ischemic brain tissue. Furthermore, it

was shown to prevent the vasoconstrictor response triggered by either 5-HT or by a calcium channel opener in vascular smooth muscle of small cerebral arteries (Ungvari et al., 1999). This may occur through the release of endothelial NO since a eNOS antagonist blocked this vasodilation effect (Ofek et al., 2012). Apparently this is a 5-HT-independent effect because it was not blocked by the non-selective 5-HT antagonist methysergide (Ofek et al., 2012). Nevertheless, whether selective 5-HT₃ receptor antagonists would alter the effect of fluoxetine needs to be assessed as 5-HT₃ receptors also mediate vasodilatation through NO (Perrenoud et al., 2012). According to Ofek et al. (2012), the indirect effect of fluoxetine involves rather an action of acetylcholine released from parasympathetic fibers and binding of this neurotransmitter on muscarinic receptors of endothelial cells (Ofek et al., 2012). This results into the release of calcium from intracellular stores in these cells and facilitates binding of calmodulin to eNOS that then produces NO from L-arginine. NO subsequently diffuses to vascular smooth muscles to induce vasodilation. Fluoxetine at low doses may also enhance noradrenaline release from cerebral perivascular sympathetic nerves and may cause, through β_2 receptors, a NO-mediated vasodilation *via* axo-axonal mechanism, independently of the endothelium (Chen et al., 2012).

2.3 Drugs Preventing Cellular Damages

As we have seen in section 1.3, neuroinflammation is one of the most important mechanisms leading to brain cell damages. A major event at the cellular level leading to the inflammation cascade is oxidative stress. Therefore, preventing oxidation stress appeared, at least in several experimental stroke models, as one of the most promising pharmacological target. Several anti-oxidant compounds have been tested clinically, including NXY-059, which unfortunately was revealed ineffective in large trials on acute ischemic stroke (Diener et al., 2008). Another important process in inflammation is immune cells adhesion and infiltration in the infarct area. Enlimomab, developed to prevent these processes, did not show efficacy in a clinical trial and had even worsen stroke outcomes (Enlimomab Acute Stroke Trial Investigators, 2001). Among the plethora of strategies researchers had hope would be beneficial in human stroke, there is also the prevention of excitotoxicity with glutamate antagonists, but these drugs also failed to fulfill expectancies (Muir, 2006).

Fluoxetine and other SSRIs shown to be clinically effective have, in turn, an interesting pattern of action at some of these same cellular processes. First, fluoxetine may inhibit cell death after stroke by blocking BBB disruption. In an experimental model of global ischemia, subchronic treatment with fluoxetine inhibited MMP-2 mRNA expression, reduced MMP-9 activity and attenuated the loss of laminin and occludin, substrates of MMPs (Lee et al., 2014). As visualized with occludin antibodies, the vascular network integrity was restored after fluoxetine treatment in ischemic animals, and this probably explains the decrease in immune blood cell infiltration concomitantly observed (Lee et al., 2014; Lim et al., 2009). Second, recent *in vivo* studies as well as studies on cultured cells indicate that fluoxetine can suppress microglial and astrocyte activation resulting from ischemic insults (Dhami et al., 2013; Lee et al., 2014; Lim et al., 2009). These therapeutic-like effects were correlated with improvements both in terms of motor activity and memory, and in terms of infarct volume and apoptotic cell death (Lee et al., 2014; Lim et al., 2009). Importantly, treatment with high acute doses of SSRIs appears particularly effective, contrary to chronic SSRI treatments that failed to induce

therapeutic effects at this level (Jolkkonen et al., 2000; Lim et al., 2009; Windle & Corbett, 2005; Zhao et al., 2005). In a co-cultured cell study, oxygen-glucose deprived cortical neurons showed greater survival in presence of activated microglial cells when they were pre-treated with fluoxetine, but not with other types of ADs such as tricyclic antidepressants, (TCA) and monoamine oxidase inhibitors (MAOI) (Dhami et al., 2013). Neurons would be protected under fluoxetine apparently because glutamate excitotoxicity resulting from microglial activation is reduced (Dhami et al., 2013). The primary mechanism accounting for the decreased glutamate release from activated microglia in presence of fluoxetine remains unclear, although interactions between serotonergic and glutamatergic systems are known to occur in the brain (Drago et al., 2011).

Fluoxetine not only influences immune cells infiltration and microglial activation, but also the capacity of these cells to produce proinflammatory agents. Protein and mRNA expression of inflammatory mediators such as TNF- α , IL-1 β , IL-6, COX-2 and iNOS and several chemokines triggered by ischemia are markedly decreased by fluoxetine (Lee et al., 2014; Lim et al., 2009). This is associated with an inhibition of NF- κ B, a transcription factor that controls DNA elements involved in cellular responses to cytokines (Lim et al., 2009).

Although drugs having a primary action on oxidation/inflammation, such as NXY-059 and enlimomab, failed to show clinical efficacy (Diener et al., 2008; Enlimomab Acute Stroke Trial Investigators, 2001; Muir, 2006), it remains possible that fluoxetine's peculiar pattern of action on glutamate excitotoxicity and inflammation explain its therapeutic action in stroke patients.

3. ANTIDEPRESSANT-LIKE EFFECTS OF FLUOXETINE IN POST-STROKE DEPRESSION

Preclinical research interest has recently shifted toward the long-term cognitive and emotional deficits of stroke. About one-third of patients display anxio-depressive symptoms after stroke onset (Carota et al., 2005; Hackett et al., 2014). Post-stroke depression is a major problem as it slows recovery, predicts poorer functional outcomes and increases the risks of mortality, including suicide (Kronenberg et al., 2014). Depression itself, which as we have seen increases the risks of stroke (May et al., 2002; Ohira et al., 2001), could be associated with BBB barrier disruption, eNO uncoupling, MMPs induction (Najjar et al., 2013; Taylor et al., 2013; Yoshida et al., 2012) and the generation of chronic small ischemic lesions (Dieguez et al., 2004). It is thus becoming urgent to adequately model at the preclinical level this stroke-depression association, especially with the prospect that drugs with antidepressant properties, SSRIs, might become the first pharmacological treatment for both the subacute and the chronic phases of stroke recovery (Kronenberg et al., 2014).

Behavioral models commonly used to rapidly screen for ADs such as the forced swim test (FST) may not be adequate. Cerebral ischemia in rodents is very often associated with motor hyperactivity resulting in decreased immobility in the FST, an antidepressant-like effect. In fact, the SSRI fluvoxamine and cerebral ischemia were shown to have additive antidepressant-like effects in the FST (Deplanque et al., 2011). Modeling symptoms of depression such as anhedonia, i.e., the inability to experience pleasure, provides more interesting information. It has been reported that MCAo can decrease by itself mice sucrose

consumption, and this was associated with a degeneration of mesolimbic dopaminergic pathways involved in reward behaviors (Kronenberg et al., 2012). Long-term treatment with the SSRI citalopram prevented anhedonia and the neurodegeneration occurring after cerebral ischemia (Kronenberg et al., 2012). MCAo alone might sometimes be insufficient to trigger anhedonia and it is often combined with a protocol of chronic mild stress to produce a depression-like state (Wang et al., 2009). Here again, at various time windows, several weeks after MCAo, chronic SSRI treatment was shown to prevent the decrease in sucrose consumption (Wang et al., 2009; Wang et al., 2010; Wang et al., 2010). As in patients, cerebral ischemia sometimes produces in rodents long term anxiety and spatial cognitive impairments that are likewise corrected by long term fluoxetine or citalopram treatments (Kronenberg et al., 2012; Li et al., 2009).

The behavioral deficits modeling post-stroke depression are associated with decreased 5-HT levels in the frontal cortex and the hippocampus (Ji et al., 2014). Serotonergic projections to brain areas involved in emotional and cognitive functions are most likely crucial for stroke recovery. Destruction of hippocampal serotonergic fibers with the toxin 5,7-dihydroxytryptamine aggravates ischemic neuronal damages (Nakata et al., 1997). Although it is beneficial to limit, not abolish, serotonergic mechanisms at the initial phase of a stroke (see section 2), on the long term, the enhancement of serotonergic transmission (as explained below) would rather favor brain remodeling and antidepressant-like behavioral effects.

3.1 Chronic Fluoxetine Increases Post-Synaptic 5-HT_{1A} Receptor-Mediated Neurotransmission

Microdialysis studies have clearly shown that 5-HTT blockade rapidly increases 5-HT extracellular concentration following either systemic SSRI injections or local SSRI injections into a brain area. However, when 5-HTT is blocked locally prior to a systemic SSRI injection, the latter induces a decrease of extracellular 5-HT concentration. This is surprising but explained by a decrease release of 5-HT resulting from activation of negative feedback mechanisms involving inhibitory autoreceptors (Auerbach et al., 1995; Hervás & Artigas, 1998). Acutely, SSRI administration decreases the spontaneous activity of serotonergic neurons, and this can obviously not explain their long-term therapeutic effect in post-stroke depression. Following weeks of treatment with these same SSRIs, the basal firing rate of neurons is re-established because of somatodendritic 5-HT_{1A} autoreceptors desensitization. A majority of authors consensually admit that this desensitization is at the core of their therapeutic effect in depression (Blier & de Montigny, 1994). Some other studies have also shown that inhibitory terminal 5-HT_{1B} or 5-HT_{1D} autoreceptors, regulating 5-HT release, might also become desensitized after chronic ADs (Chaput et al., 1986; Newman et al., 2004). Beside autoreceptors, other desensitizations occurring at post-synaptic 5-HT_{2A/2C} receptor subtypes might further explain the anxiolytic effect of SSRIs (Martin et al., 2014; Mongeau et al., 2010; Weisstaub et al., 2006). Activation of brain 5-HT_{2C} receptors during stress may indirectly inhibit 5-HT released at post-synaptic 5-HT_{1A} receptors and thereby limit the capacity of an animal to cope with stress (Mongeau et al., 2010). Similarly to other ADs (TCA, MAOIs), SSRIs are known to increase post-synaptic 5-HT_{1A} neurotransmission. Chronic SSRIs do not change the sensitivity of post-synaptic 5-HT_{1A} receptors, but rather

increase the amount of 5-HT released per action potential acting at these receptors (Chaput et al., 1991).

In the anhedonia model of post-stroke depression, animals displayed reduced 5-HT_{1A} receptor protein and mRNA levels in the hippocampus, and these changes were reversed by a citalopram treatment (Wang et al., 2009). In keeping with the view that increasing post-synaptic 5-HT_{1A} transmission leads to favorable outcomes in stroke, activation of 5-HT_{1A} receptors prevents cAMP-dependent protein kinase A phosphorylation of a NMDA receptor subunit contributing to neuronal death in the post-ischemic brain (Salazar-Colocho et al., 2007), and 5-HT_{1A} receptors may have the ability to decrease the excessive release of glutamate induced by ischemia (Semkova et al., 1998). Furthermore, differential activation of either 5-HT_{2C} or 5-HT_{1A} neurotransmission increase and decrease, respectively, cellular damages after cerebral ischemia (Torup & Diemer, 2000), while impairments of glucose uptake and hippocampal electrical activity after cerebral ischemia were both prevented by either 5-HT_{1A} receptor agonists or by 5-HT_{2A/2C} receptor antagonists (Shibata et al., 1992).

3.2 Chronic Fluoxetine Alters Trophic Factors and Cell Proliferation

Contrary to post-stroke depression, there are few neuro-anatomical correlates of major depression itself. Nevertheless, many clinical imaging studies indicate reduced hippocampal volume in depressed patients and this degeneration occurs as a function of stress chronicity and depression duration (McKinnon et al., 2009). ADs, whether or not they have a primary action on 5-HT, may induce the production of trophic factors, including BDNF. Stimulation of TrkB by BDNF triggers intracellular cascades inducing trophic effects in the hippocampus and other brain regions. The fact that tissue levels of BDNF are decreased in the brain of suicide patients and in the serum or the plasma of depressed patients (Lee & Kim, 2010) may explain, at least in part, hippocampal volume loss in these patients. Furthermore, there is a strong relationship between prior serum BDNF levels and the development of post-stroke depression (Li et al., 2014). Interestingly, the progressive fall in hippocampal BDNF levels occurring in animal models of transient ischemia was prevented by either fluoxetine or escitalopram treatment (Kim et al., 2007; Lee et al., 2011). Beyond the hippocampus, the beneficial effect of BDNF secretion following chronic SSRI treatment extends to sensory-motor cortical areas (Espinera et al., 2013; Maya Vetencourt et al., 2008). Post-stroke depression-like behaviors and the reduction in 5-HT neurotransmission are both associated with depletion of other trophic factors, such as the fibroblast growth factor (FGF-2) known to protect cerebral tissue from ischemia by activating anti-apoptotic proteins (Ji et al., 2014).

Another important recovery process that could alter hippocampal morphology is neurogenesis. It is now well-known that 1) new neurons are normally generated in this area during the whole life, 2) a decrease in neurogenesis occurs during chronic stress, and 3) the latter can be corrected by all class of ADs (Gould, 2007; Malberg, 2004; Paizanis et al., 2007). Despite being a major stress, cerebral ischemia triggers hippocampal neurogenesis, but this neurogenesis is inversely related to ischemia severity (Winkelheide et al., 2008). Neurogenesis is a mechanism necessary to reinstate some functions after brain insults since its conditional ablation attenuates recovery of motor function (Sun et al., 2012). The depressive-like behaviors of MCAo rats submitted to chronic mild stress were shown to be associated with reductions of various ischemia-induced neurogenesis processes, including cell

proliferation, survival and neuronal differentiation (Wang et al., 2008). Chronic treatments with either fluoxetine or citalopram were shown to increase hippocampal neurogenesis in experimental models of stroke, and this was correlated with improvements of late emotional and cognitive deficits (Li et al., 2009; Wang et al., 2010). Interestingly, these post-stroke improvements in terms of neurogenesis and behavioral antidepressant-like effects were accelerated by co-administration of an antagonist at the inhibitory 5-HT_{1A} somatodendritic autoreceptors (Wang et al., 2010). Furthermore, chronic buspirone, a partial agonist at post-synaptic 5-HT_{1A} receptors (and effective as fluoxetine as an anxiolytic drug) also increase neuronal cells proliferation in the hippocampus (Campbell Burton et al., 2011; Grabiec et al., 2009).

The effect of SSRIs on neurogenesis and BDNF may be implicated in neurovascular unit repair in the peri-infarct area. Citalopram was shown to stimulate neuroblasts proliferation, to enhance cells migration from the hippocampus to the peri-infarct regions, to increase BDNF protein and to improve microvessels density in the damaged cortex (Espinera et al., 2013). Interestingly, there might be a causal relationship between angiogenesis and neurogenesis stimulation by SSRIs even in treated depressed patients that had not suffered a stroke (Boldrini et al., 2012)

4. CONCLUSION AND PERSPECTIVES

Clinical studies have confirmed the efficacy of ADs, mostly SSRIs, not only in post-stroke depression but also in alleviating cognitive and motor deficits occurring after a stroke. In view of the shortcomings in the development of new pharmacological treatments for stroke, these are by any standards exciting results. Nonetheless, as argued by Cramer (2011), many questions remain at the clinical level regarding therapeutic time windows, the prognosis and the range of stroke deficits that can effectively be treated with fluoxetine or other SSRIs. Furthermore, larger clinical trials should be designed based on accumulated knowledge at the preclinical level about fluoxetine's mechanism of action. Yet, we do not really know how SSRIs exert their therapeutic effect in stroke, although several hypotheses have been reviewed here. Blocking 5-HT uptake and storage into platelets may reduce platelet aggregation and the coagulation cascade leading to either less recurrent strokes or chronic small ischemic lesions. A second possibility is the indirect vasodilator effect of SSRI *via* endothelial NO that might help reperfusion of penumbra areas. Not only would SSRI counteract hypoperfusion, they would also prevent the post-stroke increase in BBB permeability through an action on MMPs at the basal membrane of the neurovascular unit. In these two cases, by either preventing 5-HT uptake or by indirectly increasing 5-HT autoreceptor-mediated negative feedback, acute SSRIs would reduce the increased 5-HT metabolism generated by ischemia. Acute high doses of SSRIs were also shown to decrease the cellular (microglial activation) and the molecular (cytokines, chemokines) actors of the inflammation cascade and this might be explained notably by 5-HT / glutamate interactions. One may wonder, however, how important any of these mechanisms are in explaining the therapeutic effect of fluoxetine. Nevertheless, at this point, it remains reasonable to assume that fluoxetine is a pleiotropic drug exerting action on distinct mechanisms that are evolutionary linked to the role of 5-HT in defense to acute injuries.

This contrasts with our traditional views about fluoxetine being an antidepressant medication. Post-stroke depression and cognitive decline are associated with decreased 5-HT transmission. It has long been argued that chronic ADs enhance 5-HT neurotransmission, stimulate the secretion of neurotrophic factors and facilitate neurogenesis in brain areas such as the hippocampus. These physiological effects have been associated with antidepressant-like behaviors in various animal models of anxious-depressive disorders as well as in models of post-stroke depression. SSRIs might have a dual benefit in stroke; at high acute doses, or after relatively short term treatments, they would reduce post-stroke 5-HT hypermetabolism, trigger anti-thrombotic, vasodilator and anti-inflammatory mechanisms, while on the long term, SSRIs would rather desensitize autoreceptor-mediated feedback mechanisms and enhance 5-HT transmission, thereby favoring brain repair processes through neurotrophic factors and cell proliferation. Clinical studies remain necessary to determine how various fluoxetine administration protocols differentially favor short and long term recovery mechanisms in stroke patients, and to which extent any of these effects are based on either neurovascular, neuroprotectant or antidepressant actions.

Chapter 64

CORRELATION BETWEEN EXECUTIVE AND MOTOR FUNCTION IN PATIENTS AFTER STROKE

Fadilj Eminović^{1,*} and Slađana Arsić²

¹Faculty for special education and rehabilitation, University of Belgrade, Serbia

²High medical school of professional studies, Čuprija, Serbia

ABSTRACT

Executive functions refer to a number of cognitive processes that use and modify information from cortical sensory systems in the anterior and posterior regions of the brain, so they could alter and produce behavior and movement. These integrative functions, including motor and behavioral components are necessary for effective aimed actions that represent base for performing activities of daily living. The most important components of executive functions are selection of the goal, planning, inhibition of irrelevant responses and impulse, monitoring and control activities, as well as the evaluation of the action outcome. Attention control, working memory and temporal organized behavior, also stand out as a special executive functions.

Cognitive impairment after a stroke may be complex, particularly for the involvement of the cerebral hemisphere or the frontal lobes, and depending on the lesion, executive function could be more or less effective. The function of the walking is the most compromised motor function.

The subject of this study was to examine the correlation between executive functions, attention and walk disorders after a stroke and how that relation influences the recovery process and achievement of functional independence in patients. Within the aim of the research, the relation between the levels of organization activities, attention and walk disorders in patients after a stroke had been analyzed.

The examined sample consisted of 50 patients after a stroke, included in the rehabilitation process and 50 patients randomly chosen, matched by age and general characteristics, which in its medical history and neurological examination, had no symptoms of acute or chronic neurological disease. For the evaluation of executive functions, attention, cognitive state, the Tests for the evaluation of motor functions

* Corresponding Author's Email: eminovic73@gmail.com.

including the evaluation of all gait parameters and the Test for the evaluation of functional abilities have been used in the paper.

The received results show that the patients after stroke have a statistically important lower achievement at the Test for evaluation of attention ($p < .001$), a statistically important lower achievement at the Test of executive functions ($p < .001$), that 72% of examinees have a minor cognitive disorder, while 6% of the examinees have a major cognitive disorder after a stroke. The obtained results also show a statistically important lower efficiency in all examined motor functions, in the gait frequency ($p < .01$), gait speed ($p < .001$), the length of pace ($p < .001$), the motor leg index ($p < .001$), obstacle management and balance keeping ($p < .001$). The results confirm the existence of a statistically important difference in all examined variables between the two groups of examinees ($p < .001$). A statistically important difference in results of the right-sided and left-sided hemiparesis of the examined patients after the stroke had been noticed at executive functions ($p < .05$), while at motor functions the difference is of no statistical importance. Within the group of after-stroke patients there is a statistically important link between the level of cognitive damage and the examined parameters of walk ($p < .05$). Furthermore, within the group of after-stroke patients there is a statistically important link between the level of cognitive damage and functional ability ($p < .05$).

Keywords: Stroke, executive functions, cognitive functions, attention, walk, functional recovery

INTRODUCTION

A stroke as a widespread medical problem is for some time undergoing the different stages of the great interest of various experts who deal with this problem. In assessing the significance of this disease one should bear in mind that the stroke is one of the leading causes of functional disability.

According to the World Health Organization (WHO, 1980) stroke is a clinical syndrome of vascular etiology that is characterized by the sudden onset of focal or global cerebral deficit lasting more than 24 hours or ending in lethal outcome. World Health Organization data show that, despite diagnostic and therapeutic possibilities, stroke is the third most common cause of death in the world (right after cardiovascular disease and cancer) and the second most common cause of functional disability (Goldstein et al., 1989).

The data that indicates a high degree of functional disability, which ranges from light (35.8%), moderately severe (33.3%) and severe (30.9%), gives cause for concern (Peterea, 2009). Having in mind the current statistics, the role and importance of medical rehabilitation is quite understandable.

Cognitive deficit within the stroke has numerous significances. It is assumed that there is dependence in quality of motor recovery and improvement in functional status with the degree of preservation of cognitive function. It is important to do a functional assessment which includes an assessment of cognitive functions prior to the rehabilitation process of patients after a stroke.

Traditional cognitive assessment includes the use of tests for assessing the achievements and measurement of specific cognitive functions. Many of the tests are well standardized in the general population, while some of them are still developing, all in aim of finding the most sensitive tests for detecting subtle brain function disorders, of any kind of genesis.

In few recent decades many experts have been involved in the issue of cognitive deficits as a part of stroke, as well as the impact of existing connections with motor disorders, with an emphasis on walking function in patients after a stroke. Preservation of cognitive function is of particular importance for the rehabilitation of patients after a stroke. According to cognitive competence, a patient after a stroke during the rehabilitation process will be able to set a goal for himself and to assess the real possibilities of achieving that goal. The multiple cognitive impacts on walking and link between movement control and appropriate behavior during the walk had been observed. It is manifested by consciousness of the individual about destination, the ability to appropriately control limb movement that produce walk and the ability to move through often very complex environment, in order to successfully reach the desired destination. Up until recently, walk was considered mainly as an automatic motor task which requires minimal cognitive engagement on a higher level. However, growing evidence link changes in the ability to organize activities and attention to the present irregularities of walk (Seligman et al., 2008). One of the major goals of the rehabilitation process is to help the patient to achieve the highest possible level of functional independence, in which walk is the basic component of independent functioning. It is assumed that this approach to the rehabilitation can have a positive reflection on the course and outcome of rehabilitation treatment.

Therefore, guided by the experience of all those who have dealt with this problem, while adhering to all the rules in monitoring clinical characteristics of cognitive competence and functional recovery, we have reached the yet unexplored field that connects the executive function and motor impairment in patients after a stroke. If we have chosen a good path and contributed to a better understanding of this problem, we can be somewhat satisfied with what we have tried to do. Perhaps future research stimulated by this work and previous works in this field will be able to highlight the importance of this problem and clearly define the link between cognitive dysfunction and motor damage after a stroke, as well as to create new opportunities and make appropriate treatment programs and to implement them in the process of medical rehabilitation, fully supporting them.

Organization of Neuropsychological Functions Responsible for Planning and Organizing Activities - Executive Functions

Prerequisites for the development of planning and organizing activities lie in the complex functioning of the psychological functions represented in hierarchical and dynamically organized neuroanatomical systems. The theory of functional systems relies on the dynamic localization of higher mental functions. In accordance with this theory, the anatomical basis of cognitive functioning is consisted of three hierarchical functional blocks.

Luria (Luria, 1983) considers that for understanding complex forms of mental functioning it is often necessary to clarify the structural and functional basis of brain machine. With relative precision he distinguishes the following three functional blocks: a block of maintaining the state of alertness and awareness, block the receipt, processing and storing exteroceptive information, programming block and control of voluntary activities based in the frontal lobes.

All three functional blocks are involved in the organization of any kind of complex mental activity and behavior. Having this perceived, the higher mental functions present

complex, hierarchically structured functional systems whose links are afferent and efferent type deployed in the distributed, remote cortical and subcortical regions of the brain. General properties of functional systems have a high degree of plasticity, mutual functional interactions and the possibility of their reorganization after the effects of pathological factors. Based on that, every psychic function relies on the joint work of different parts of the brain which are part of the given functional system. One and the same psychic function can be damaged at various locations of brain injury, but the quality of dysfunction will be specific for a particular area (Očić, 1988).

Neurobiological Basis of Executive Functions

The main feature of the prefrontal area is late maturing. In the prefrontal cortex three main functionally distinctive areas can be distinguished:

- Dorsolateral area - located on the outer side of the prefrontal cortex, the phylogenetically youngest part of the prefrontal cortex with rich reciprocal projections from the posterior association areas that integrate visual, auditory and somatotask data.
- Mediobasal area - focused on the anterior part of the cingulate cortex, which surrounds the corpus callosum. It has the richest links with structures that are considered relevant for memory, but also for other cognitive processes.
- Orbitofrontal area - has intense two-way connections with the amygdale, which enable a special role of "mapping" internal information such as motivation and emotion.

The frontal - subcortical circuitry should be mentioned - the loop of the frontal cortex with subcortical structures, such as anterior cingulate areas form a network for auto-regulative processes, initiative, and motivation, cognitive control of attention, concentration, and integration of complex information.

Functional Organization of the Frontal Lobes

Stuss and Benson (Stuss, 2002) have incorporated in their interpretation of functional organization of the frontal lobes the basic Luria settings, that is the concept of programming, control and regulation of behavior by emphasizing the function of self-awareness. This highest level of functioning of the frontal lobes, as well as an exclusive feature of the human species, is comparable to the concept of metacognition considering that self-consciousness includes introspective ability, and knowledge of their own knowledge. In the case of frontal lesions, it is the inability to use otherwise preserved knowledge about their own condition in order to regulate behavior, which manifests in the inability to self-observe, self-assess the problem, to grasp their consequences and make the appropriate decisions (Očić, 1988).

Model of cognitive control of Norman and Shallice's (Krstić, 2011), is based on the idea that there are two levels of behavior control: the lower level is used to start a number of

activities that arise without conscious intention, and parallel with other activities; a higher level of control behavior, for whose involvement is needed a conscious decision with adequate preparation and the execution itself is controlled by Supervisory Attentional System (SAS). According to this hierarchical model, the first level of cognitive architecture consists of specific cognitive units related to perception, language and practices. By their integration the behavioral patterns necessary for the control of routine activities arise on the other levels. The third level corresponds to the routine selection of mutually competitive cognitive schemes and functions by well-established rules in familiar situations. In new and unfamiliar situations which require suppression of habit, the activation of top-level cognitive control of SAS occurs. The model of supervisory attentional system includes a two-step control of executive motor and mental actions. This system renews its functions through modulation of activities in lower level on a flexible way by changing patterns of behavior. This highest level of cognitive control is in the responsibility of the prefrontal cortex, and the absence of its functions (in case of damage) is expressed through the rigid and perseveration behavior which is in the power of lower-level cognitive control (Očić, 1988).

Basic Executive Functions

Although today there is no absolute agreement on the separation of the most important components of executive functions, most often as with Luria (Luria, 1983), include aim selection, planning, inhibition of irrelevant responses and impulses, monitoring and regulating activities, as well as the evaluation of action outcomes. Voluntary attention control, working memory and temporal organization of behavior, also stand out as a special executive functions (Krstić, 2011). Working memory - such as by Badli stated (Baddeley, 1986) can be viewed as a multi-component system, whose function is to periodically store and manipulate information. This system, especially its control component is considered to be a prerequisite for the planning, selection and action control. Behavior disorder and patients cognitive impairments of executive functions is named Dysexecutive syndrome, and becomes regularly used in the scientific literature. Inhibition - is necessary for the smooth maintenance of a "mental set". In the base of behavioral inhibition three interrelated executive inhibitory processes exist: inhibition of the predominant responses; stopping initiated responses, control of interference. Temporal Coding - is very important executive control mechanism of information delay in short-term memory (Baddeley, 1986).

The Concept of Executive Functions

Even Lezak (Lezak, 2004) in her mid-career work indicated that the executive functions consist of skills that allow a person to successfully engage in independent, purposeful and self-contained behavior. According to the initial treatment she explains the role of executive functions in four categories:

- Formulation of intentions - is in accordance with the subject's needs and desires and designs their implementation in the future. This behavior is determined by the

concept of a purpose. It includes motivation, insight into their self-psychological and physical characteristics, as well as relation to the environment. Her clinical correlate makes apathy, difficulty in carrying out an activity without environmental stimuli and instructions, passivity and inertia.

- Planning - includes the ability to specify the strategy which will be implemented and the intentions of the aim with learning to distinguish between desires and real circumstances, anticipating through the consideration of alternatives and affiliation. Necessary conditions of effective planning are good impulse control, good capacity of maintenance attention and memory.
- Performing planned activities - includes its realization through self-initiation of integrated behavioral and physical activity, maintenance, stopping and changing individual behavior and movement sequences. Productivity and flexibility are the indicators of self-regulation movement and behavior. Clinical correlate makes a global slowing and the impoverishment of behavioral patterns and movements, perseverative, stereotypes and lack of adaptation.
- Efficiency of achievement - includes the ability of monitoring, self-correction and quality control aspects of behavior. Dysfunction of this component is assessed by analyzing the nature of errors, the patient's ability to grasp, his reactions to them, and behaviors that are used to overcome them (Očić, 1988).

Stussy and Benson (Stuss, 2002) almost identically defined executive functions, including the capacity to anticipate, set aim, plan, activate a number of attempts, and verify the results and comparison to the planned ones. The same authors report an interesting fact that one of the phylogenetically youngest brain structures - prefrontal cortex - is crucial for the highest human mental attributes, or the function of self-consciousness.

The Role of Executive Functions in Motor Activity and Walk

Up until recently, stroke was generally regarded as a mostly automatic motor task, which requires minimal cognitive engagement to a higher level. Growing evidence, however, link changes in executive function and attention aimed at healthy walk and walk with disabilities (hindered rotation). The relationship between executive function and attention and the walk itself becomes more important when monitoring patients with irregularities while walking. Multiple neuropsychological impacts on walking and interdependence of movement control and appropriate behavior are connected by cause and effect. It is manifested in the part of the individual awareness of the destination, the ability to adequately control the limbs which produce walk and mobility through the often complex environment in order to successfully get to the destination. Methods of visualization demonstrate, that is show the involvement of frontal activity during the movement. This review covers the importance and relevance of two specific cognitive function, executive function and attention in deriving walk during normal walking as well as in pathological conditions.

Executive functions refer to a number of cognitive processes that use and modify information from many cortical sensory systems in the anterior and posterior regions of the brain in order to change and produce both behavior and movement. These integrative

functions including motor and behavioral components necessary for effective targeted actions are the basis of the ability to perform activities of daily living.

The role of prefrontal areas in motor functioning refers to the ability to master the specific mechanisms that allow individuals a certain level of motor competence in the implementation of independent, purposeful goal-directed behavior. Since the frontal areas are composed of a number of subsystems, which are carriers of various functions and as these systems mature at different speed, their role in motor functioning can be viewed by following certain mechanisms of motor expression, which harmoniously compile motor functioning as a whole. The wealth of functions, its position and participation in the various components of human activity, indicate that their importance in motor performance is reflected through clearly differentiated, organized and properly executed motor actions.

Biomechanics of Human Movement and Characteristics of Effective Walking

The man's walk assumes an upright position and consists of a series of rhythmic body movements, which are accompanied by postural adjustment, that aims to move the body from one point to another in terms of the most efficient ways of using energy. Mostly simplified, the walk can be seen through the way of moving the gravity line that is set directly in front of the first sacral disk. The center of gravity is considered to be the most important factor in monitoring the course of walk, although it moves only a few inches vertically and laterally within the pelvis. These shifts are important in "absorbing" ground reaction force. In studying walking patterns, it is usual to start with walk cycle that begins when one foot makes contact with the ground and ends when the same foot again starts this contact. With this in regard, the cycle of walk is defined and analyzed. The walk cycle is a period between the ipsilateral (equilateral, isosceles) contacts on the feet and it is divided into two phases or two periods: a) phase support - which means the foot contact with the ground, b) phase pendulum - which means the absence of this contact.

Normal walking pattern or walk of a healthy individual (effective walk) is easily recognized because it represents a rhythmic cycle that repeats itself in a coordinated manner. The effectiveness of the walk is observed as followed: a) the stability in the support phase on both and on one leg; b) The efficient transfer of weight from one leg to another, running rhythmically and relatively fast setting foot during the swing phase of support and c) alternative transfer and movement of the body weight forward, which is happening the most during the swing phase. Related to the aforementioned, the walk is often defined as the movement of the center of gravity in space that requires the least energy consumption (Pavlović, 2006).

Kinematic Walk Analysis

Under the kinematic elements the scope and the direction of movement are implied, but not the force. In the frame of tracking the kinematic analysis, the walk is accompanied by a characteristic scheme and eventual deviations from normal. Starting the walking activity of the hip flexors, there is a mild abduction and external rotation of the hip joint until the moment of the heel support, when scheme changes quickly in the direction of adduction and

internal rotation which last during the time of load. Adduction here is the result of lowering the pelvis contrary to the support and the palm-phase pelvis in a neutral position, the hip is rotated inside and trunk begins to move in order to facilitate the transfer of weight.

Walk Parameters

Spatial walk parameters represent monitoring and measuring foot contact in the time area during the walk cycle: length of the pace is the distance at which one foot is placed in front of the other (normal 37.5 to 50 cm) and the length of the double pace ("Strida") is the distance between the two successive set of the same foot (normal range 75 - 100 cm). Shoes and height of a person have a direct impact on this segment.

Temporal walk parameters are related to the time in the walk cycle and include the duration of the support phase, the duration of the swing phase, during single support, double support time and time overall walk cycle. The combination of temporal and spatial parameters, allows the calculation of the speed of walking. Walking speed affect the kinematics.

The usual normal walking speed on ground level is 82 m/min. Adult males were 5% faster (90 m/min), women were 6% slower (77 m/min). The number of paces varies from 70 to 130 per minute. The ratio of time spent in different stages of the walk, also varies with speed. When walking faster, the length of paces increases and the increase in speed results in a proportional phase of extension and shortening of the phase of the oscillation of the support phase.

Locomotor Activity and Movement Control

In the walking control of the man the large number of components of the motor mostly motor cortex, basal ganglia, cerebellum, and parts of the reticular formation of the spinal cord are included. Determination of these structures was realized in many ways, primarily by registering increased electrical activity of their neurons during walking, and electrical stimulation of these regions leads to the appearance of movement similar to walk. By involving large number of structures of the CNS during walking witnesses the complexity of this seemingly simple motor action. This is clearly seen in the analysis of mechanisms of walking: alternating flexion and extension of the limbs; successively shifting the body weight from one foot to the other while maintaining impeccable balance and a certain body posture.

Cortex has multiple roles in the process of walking. Thus, motor cortex receives not only somaesthetic, but the vestibular and visual information. Based on this information forms the representation of space in the CNS, that is the reference axis related to the objects in the environment and in relation to the effects of gravity. This spatial pattern may be required for carrying out movements in the space for walking. Second, programs for sequences of voluntary movements involved in locomotion are encoded in the primary motor area, where it was sent by corticospinal tract in the spinal cord. Basal ganglia with motor cortex have a very important role in locomotion. They perform the integration of visual and proprioceptive information, then participate in the corresponding sequence of movements necessary to locomotion, and perform the initiation and cessation of walking.

Balance and Balance Disorders

Balance is the ability to keep the body above the surface of the support in a variety of anti-gravity conditions. This is coordinated muscle groups activity that opposes gravitational forces, which is a prerequisite for the development of good posture, ability to maintain attitudes, performance and movement skills acquisition. Balance is not static, it means continuous alignment position whether to make a barely perceptible movement or to make a change in tone. Balance basically involves an integrated response development of labyrinth and optical erection, development of balance reactions and their integration with proprioceptive and tactile sensations. Good balance and good posture mean that the postural reflexes well developed and automated.

The loss of one sensor is a kind of serious disorders, although information from other areas of well-compensated for these deficits. Balance depends on many factors: the mature central nervous system, of pathological changes in the CNS, the mobility of joints, mobility of the spinal column, the mobility of the limbs, muscle strength, the state of the sensory organs, the presence of pain, the surface of support, the weight, height, etc. The disorder was any of these factors in any form may lead to disturbances of balance.

Motor Functions and Walk in Patients After a Stroke

In typical circumstances, walk is the automatic activity in which you do not pay attention to the sequence of execution. You start walking activity voluntary, and centers in the central nervous system, take over the role further on, until the execution of the activity. In situations of the damaged central nervous system, such as after a stroke, the scheme or the majority of them are no longer present. Then the patient has to adapt to new circumstances and benefit schemes available to him/her. Kinematic and kinetic aspects of locomotion in these patients vary depending on the severity of the damage, the degree of recovery and the use of various compensatory mechanisms. Classically recognized is the scheme of "circumduction while walking." The energy consumption of these patients compared to the normal walking is significantly higher. The dynamics of the recovery of the walk and function of the lower extremities is done through various stages hierarchically arranged according to the conquest of certain activities of the movement (Pavlović, 2006). By following the course of recovery one must bear in mind that each patient has "their plateau" of recovery.

The study conducted on patients after a stroke in the rehabilitation process show the usual kinematic characteristics of walking. Walk as a significant functional activity in a patient after a stroke, is a process which is carried out in phases. It starts with a phase of practicing motor control with an emphasis on symmetry in all positions. It is believed that the neurophysiologic preparation for relatively satisfactory scheme is done when they gain control over some of the major muscle groups of stroke. At the time when motor activity is dominated by the basic pathological synergy, in a post-stroke patient, individual compensations related to weight of damage could be expected, which essentially contributes to the complication of abnormal patterns. Therefore, when it comes to practicing motor responses of the lower extremity necessary for walking, with the emergence of voluntary movements, one should go on practicing a combination of the so-called functional movement patterns required for walking (the elements necessary to support phase and phase swaying).

When conditions are right, the practicing walking in all directions is followed. In direct coaching, a slow pace is first used for the purpose of practicing and emphasizing each phase of walking (Pavlovic, 2006).

From the standpoint of biomechanics, synergies are considered to be co-ordinated actions of joints and muscles in order to achieve the set goal. Within the clinical neurorehabilitation, motor synergies are usually defined as stereotyped movements of the whole limb which suggest the loss of independent joint control and limited ability to coordinate. The walking schemes thus become less adaptable, making it difficult for the performance of a large number of functional motor tasks. In the framework of neurorehabilitation synergies are considered side effects, and treatment is aimed at "breaking synergies". These synergies are called obligatory, and the most basic division is on extension and flexion synergy.

Early walk, which means the neutral walk, which is not yet won stability and controlled mobility can be a motivational mechanism for activation of the patient, but it entails great risk of unwanted and often unexpected deviation in a given activity. Therefore, it is considered that a functional walk should practice, once in a standing position one can gain satisfactory level of balance, and controlled mobility (Pavlović, 2006).

Problem and Objective

The aim of this study was to investigate the correlation between ability to organize activity and attention, and walk disorder in patients after a stroke, and how that relationship affects the achievement of functional independence of patients.

The ability of planning and organization of activities as a cognitive trait that allows precise strategies that will be implemented and the intentions of the aim, represents the highest level of functioning of the frontal lobes. The ability of planning and organization activities is a privilege of a human and is comparable to the metacognition that is, with awareness of their own knowledge. It includes all the components from which the "goal-directed behavior" derives and that is formulation of intention, action planning, carrying out planned activities and verification of actions performed. The ability to organize activities is based on a cognitive process which use the modify information from many cortical and sensory systems in the anterior and posterior regions of the brain, and thus to control, modify, and produce activity. It is linked to the functioning of the frontal lobe of the brain and the corresponding network. The area of the prefrontal lobe is associated with cognitive aspect of the ability to organize activity (EF), the anterior parts are included in the aspect of the behavior of self-regulation (inhibition and self-awareness), while the back parts are included in the process of concluding. Neuroimaging studies that attempt to determine the topographic frontal lobe activity, show inconsistent results (Collette et al., 2008) and suggest that different tasks intended for the functions of the frontal lobes activate not only different frontal areas, but other areas of the brain.

Cognitive impairment after a stroke may be complex, particularly in the involvement of the cerebral hemisphere or the frontal lobes, because depending on the lesion, executive function will be more or less effective. One investigative study suggests a significant association of the left frontal lobe damage and particular characteristics of executive functions (for example - the ability to plan), while damage to the right frontal lobe are of great importance to the quality of executive functions. This study highlights the importance of

multicomponent approach to the assessment and rehabilitation of patients with stroke (Jodzio, Biechowska, 2010). Function of walking is from all motor functions commonly affected. The walk of healthy people provides the basis for the assessment of pathological walk and ways of resolving the dysfunctions. In the control of human walking a large number of components of the motor system, primarily motor cortex, basal ganglia, cerebellum, parts of the reticular formation and spinal cord is included. Cortex plays an important role in the process of walking, it is provided not only by somaesthetic but vestibular and visual information as well. Based on this information the representation of space in relation to objects in the environment and in relation to the effect of gravity is formed, this spatial pattern is necessary for the execution of movement in space and walking. The programs for voluntary movement sequences involved in locomotion are encoded in the primary motor area. By identifying the role of specific structures of the CNS in function walk it can be reached in several ways: by registering increased electrical activity of their neurons during walking, by electrical stimulation of specific areas that cause similar movement speed and specific test techniques and procedures that can be linked cognitive and motor function.

Anticipating the possibilities and limitations in patients after stroke, the aim of this study was to determine the relation between the ability to organize activity and attention to irregularities while walking. Determination of cognitive competence (or dysfunctions) and the dysfunctions walk in patients after a stroke, is within the scope of the theoretical part of this study. Practical significance of the research will have full confirmation if the established connection is important for the application of medical rehabilitation and enable the achievement of a high degree of functional independence of patients after stroke. Since the achievement of functional independence of one of the leading and final goal of medical rehabilitation of patients after stroke, and that the presence of cognitive deficits may affect the course and outcome of the end of the process, the scientific justification for this research is the multidisciplinary approach to the diagnosis, and in treating these patients.

RESEARCH METHODOLOGY

Basic methodological principles of research is based on the comparison of results between the two groups of respondents, which consisted of the evaluated patients after a stroke and patients without neurological damage, in order to identify possible differences between individual variables of the research. Kao as a target study the differences within the group surveyed variables in post-stroke patients with cognitive impairment and without cognitive impairment will be analyzed.

Research Instruments:

Wisconsin Card Sorting Test - WCST

The main purpose of this test is to detect perseverativity and mental rigidity of the surveyed companies. The ability to plan and organize activities as cognitive trait that allows precise strategies by which will be implemented the intentions and the accomplished aim represent the highest level of functioning of the frontal lobes. Desires or will, planning,

anticipation, intent implementation and verification of the performed actions were assessed by WCST - Wisconsin card sorting test (Heaton, 1981). It is card sorting test and the most popular test for detecting perseverativity and mental rigidity. It was primarily for assessing abstraction in healthy respondents.

Trail Making Test - TMT A/B

This is a test of the neuropsychological test battery box and is used for evaluation of the flexibility of attention. The attention is the direction and focus of mental activity to something specific, whereby the orientation is determined by selectivity and duration, and focus by the possibility to ignore distraction. Attention has been tested using the TMT A / B test. It has been recognized since its inception as a technique sensitive to the effects of brain damage in general (Reitan, 1958).

Mini Mental State Examination - MMSE

Mini Mental State Examination - MMSE is a test for evaluating the cognitive state of patients, screening option, easy-to-use, sensitive and gives valid results. Source: Folstein MF, Folstein SE, McHugh PR., (1975): "Mini-mental state: a practical method for grading the cognitive state of patients at the clinic," J Psych.

Functional Ambulation Category - FAC

The test is intended to assess the quality of movement and performance of motor tasks in patients after stroke. Functional Ambulation Category - FAC test or functional test movement (Holden et al., 1984) is a simple measuring instrument that includes assessment of walking ability in hemiplegic patients. The test has six terms.

Step Test

Step test (Hill et al., 1990) is primarily used to assess the ability to perform motor task in overcoming certain obstacles including spatio-temporal parameters and balance. In this test evaluates the index of the feet of the motor (Motoricity leg index).

Functional Independence Measure - FIM

The main purpose of the test is to assess the functional independence of patients with neurological impairments. The achievement of functional independence is leading and final goal of medical rehabilitation. FIM test with a minimum of data provides an adequate, prompt, valid, general assessment of functional capacity of patients with neurological impairments and as such is accepted in the world. FIM test covers six areas, and within these areas the eighteen tasks.

RESEARCH RESULTS

General Characteristics of the Sample Survey Results

The sample after a stroke consisted of 50 subjects, female = 24 N (48%) and males n = 26 (52%). These were the patients that were included in the process of rehabilitation after a

stroke. The range of their age was from 54 to 80 years, mean value (hereinafter referred to as AM) was 69.99 years, the standard deviation (hereinafter referred to as SD) was 7.71 years . 22 patients (44%) who had a right-hand hemiparesis and 28 (56%) dextral hemiparesis.

The sample of individuals without neurological damage also consisted of the 50 respondents, females N = 27 (54%) and males N = 23 (46%), selected randomly, in the appropriate age. Their age range was from 51 to 82 years, M = 67.18 years, SD = 9.27 years. This group of people consisted of persons who did not have in their history any neurological findings of symptoms of acute and chronic neurological diseases, Parkinson's disease, multiple sclerosis, dementia and depression.

Statistical tests that were applied for assessing differences between the groups have shown that the group of persons after a stroke and the groups of individuals without neurological damage did not differ significantly in terms of gender, age and educational structure, they differ.

Significantly in terms of marital status, among persons after stroke compared to a group of people without neurological damage more than one person was in a marriage, a small number of divorced and those who are unmarried / single. Risk factors for hypertension and type II diabetes was significantly more common in the group of persons after the stroke than in the group of individuals without neurological damage (Table 1).

Table 1. Shows structure of groups of patients in terms of demographic characteristics and risk factors and test results for testing the statistical significance of differences between groups in terms of these characteristics

Characteristic		Persons after a stroke	Persons without neurological damage	The value of statistics for testing the difference	Stat. Signif.
<i>Gender</i>

TMT B					t(72) = -19.38, p<.001				t(72) = -9.04, p<.001			

Table 3. Shows statistical significance of differences in results of the tested flexibility of attention and visuomotor tracking application TMT A / B test between a group of persons after a stroke and a group of persons without neurological damage

Parameter	Persons after a stroke	Persons without neurological damage	U	r
	Middle range	Middle range		
TMT A	61.93	37.57	603.50 ***	.42
TMT B	67.66	32.07	328.50 ***	.64

Legend: U - value of the Man-Whitney (Mann-Whitney) in statistics, r - effect size.

People after a stroke from the sample have significantly statistically higher average value of the parameter TMT A from normative value, $t(72) = -12.38$, $P < .001$, and significantly higher values of the parameter TMT B from normative value, $t(72) = -19.38$, $p < .001$. In individuals without a neurological damage of TMT is determined by the value of A $t(72) = -9.21$, $p < .001$, and the TMT B, $t(72) = -9.04$, $p < .001$.

Table 4. Shows results of tested planning skills and perseverativity by applying WCST test for a group of patients after a stroke and a group of subjects without neurological damage

Pers.er.	t(73) = 2,73, p<.01 t(73) = 5,69, p<.001									

Legend: Categ. - Number of categories; Pers. er. - Number perseverative errors.

The results of the Mann-Whitney tests show that a group of people after a stroke had in average higher value of the parameter TMT A in relation to the group of persons with no

neurological damage, $U = 603.50$, $p < .001$, and the effect size was moderate ($r = .42$). Also, persons after a stroke in average had higher values of the parameter B TMT from persons without neurological damage, $U = 328.50$, $p < .001$, and the effect size was large ($r = .64$).

The results of the Mann-Whitney tests showed that the group of patients with post-stroke hemiparesis of the right hand did not differ significantly in terms of the parameter TMT B (mean range = 23:47) from subjects with hemiparesis of the left side (mean range = 20:94), $U = 523.50$, $p = 0.40$.

The results of t-test showed that persons after a stroke in our sample had significantly lower number of categories on the WCST test compared to the normative sample, $t(73) = 12.36$, $p < .001$. Perseverative errors were statistically significantly lower among persons after a stroke compared to the sample values obtained by the sample normative test, $t(73) = 2.73$, $p < .01$.

Persons without neurological damage from the sample had an average of a statistically significant number of categories in WCST test compared to the test norms, $t(73) = 10.49$, $p < .001$. Also, they had a statistically significantly lower number of perseverative errors compared to the test norms, $t(73) = 5.69$, $p < .001$.

The results of the Mann-Whitney tests show that a group of people after a stroke in average achieved fewer categories (MDN = 1) than people without neurological damage (mdn = 2), $U = 729.50$, $p < .001$, effect size was moderate ($r = .35$). Also, the persons after a stroke in the average had more perseverative errors (mdn = 8) compared to the persons without neurological damage (mdn = 2:50), $U = 509.50$, $p < .001$, the effect of group membership of the difference is large ($r = .51$).

Results Mann-Whitney tests showed that subjects with post-stroke hemiparesis of the right hand achieved significantly lower (.05 significance level) the number of categories (mean rank = 18:16) on the WCST than respondents with hemiparesis of the left side (mean rank = 26.54), $U = 155.00$, $p < .05$.

Table 5. Shows statistical significance of differences in the results of the test planning skills and perseverativity by applying the WCST test between groups of persons after a stroke and a group of persons without neurological damage

Parameter	Persons after a stroke		Persons without neurological damage		U	r
	Middle range	mdn	Middle range	mdn

Legend: Categ. - Number of categories; Pers. gr. - Number of perseverative errors; MDN - median, U - value of the Mann-Whitney in statistics, r - effect size; *** $p < .001$.

Table 6. Shows that among the persons after a stroke, 22% of them categorized as with no cognitive impairment according to the MMSE test results, 72% in the category of mild cognitive impairment, and in 6% of test results indicating severe cognitive impairment.

Among subjects without neurological damage, no person were found with mild and severe cognitive impairment according to the results of the MMSE test.

Table 6. Tabulation of the level of cognitive functioning of examinees after stroke and the examinees without neurological damages of MMSE test

Total of points	Damage	Persons after stroke N(%)	Persons without neurological damage N(%)
24-30	Without cognitive damage	11(22)	50(100)
18-23	Light cognitive damage	36(72)	0(0)
0-17	Severe cognitive damage	3(6)	0(0)
Total		50 (100)	50 (100)
$\chi^2 (2, N = 100) = 63.93, p < .001.$			

The Chi-squared test showed that the difference between the two groups in terms of belonging to certain categories of cognitive impairment (non impairment) is statistically significant at 0.001, $\chi^2 (2, N = 100) = 5.15, p < .001$.

The results of Mann-Whitney test showed that there were no statistically significant differences in the level 0 .001 between the two groups of respondents in terms of average scores on FAC test, $U = 302.00, p < .001$, effect size was large ($r = .69$). The patients without neurologic defects have an average score of FAC (mdn = 5) compared to the post-stroke patients (mdn = 2).

Table 7. Shows the results obtained by evaluation of walk in patients after a stroke and patients without neurological damage by applying a functional test of movement

FAC score	Persons after a stroke		Persons without neurological damage

Table 11. Shows the results of measured walking speed compared to normative values in patients after a stroke and patients without neurological damage, and the statistical significance of differences in walking speed between persons after stroke and those without neurological damage

Grou		Walking speed (m/min)						U	r
		MV	SD	mdn	min	max	Midle range		
Norms	Men	86	/	/	/	/			
	Women	77	/	/	/	/			
Persons after a stoke	Men	10.48	5.06	8.11	5.45	20.00	25.74	12.00 ***	.85
	Women	7.59	1.61	7.28	5.50	10.71			
Persons without neurologila damage	Men	34.03	8.57	31.58	19.35	54.55	75.26		
	Women	26.59	15.79	66.67					

Legend: min - minimal determined value, max - maximal determined value, MV - mean, SD - standard deviation; MDN - median, *** p <.001.

According to the Mann-Whitney test (Table 10), persons with no neurological damage had in average, a higher frequency of walk (mdn = 45.71) compared to persons after a stroke (mdn = 52.16) and the difference is statistically significant at the 0.01 level, U = 851.50, p <.01, and the magnitude of the effect is small (r = 0 .27).

Results Mann-Whitney tests showed no statistically significant differences in the frequency of walking between subjects with right-hand hemiparesis (mean range = 24.13) and hemiparesis of the left side (mean range = 22:17), U = 225.50, p = . 62.

Table 12. Shows the results of measured length of steps in patients after a stroke and patients without neurological damage and statistical significance examinations of differences in the length of stepping between the groups

Step length (cm)						
	min	max	MV	SD	mdn	Middle range
Persons after a stroke	14.00	35.00	23.28	5.39	23.00	25.84
Persons without neurological damages	26	75	52.28	8.29	52.00	75.16

Legend: min - minimal determined value, max - the highest determined value, MV - mean, SD - standard deviation; MDN - median, *** $p < .001$.

According to the Mann-Whitney test (Table 11), persons without neurological damage in average, had a higher walking speed (mean rank = 75.26) than persons after a stroke (mdn = 25.74) and the difference is statistically significant at 0.001, $U = 12.00$ $p < .001$, and the effect of group membership on the walking speed was high ($r = 0.85$).

The results of the Mann-Whitney tests showed that the group of patients with post-stroke (hemiparesis lat. Dextre) right-hand hemiparesis did not differ significantly in terms of walking speed (mean rank = 25.08) than subjects with (hemiparesis lat. sinistri) left hemiparesis (mean range = 21:48), $U = 207.50$, $p = 0.36$.

The Mann-Whitney tests results showed that patients without neurological damage, in average, had significantly higher assessment of foot dorsiflexion in patients after a stroke, $U = 48.50$, $p < .001$, and the effect of group affiliation on the result was large ($r = .94$) (Table 13).

Also, the results of Mann-Whitney test (Table 13) showed that the patients without neurologic defects had a higher score in average of knee extension in post-stroke patients, $U = 221.00$, $p < .001$, and the effect of group affiliation on the result was large ($r = .81$).

Results Mann-Whitney test (Table 13) showed that patients without neurological damage, in average, had significantly higher hip flexion in patients after a stroke, $U = 375.00$, $p < .001$, and the effect of group affiliation on the result was large ($r = .70$).

Gait frequency (number of steps in min.)	33.91	23.13	122.00*	.21	.87
Stride length (cm)	36.77	22.32	90.50*	.29	.004

The difference between two groups of patients, regarding the affiliation to balance maintenance categories by STEP test, is not statistically important according to Mann-Whitney test results, χ^2 (2, N = 50) = 1.90, p = .270.

The Mann-Whitney test results showed that there was no statistically significant difference in gait speed, U = 161.00, p = .190, in stroke frequency, U = 165.50, p = .229, and the stride length, U = 150.00, p = .115, between persons after stroke, which differ in respect to TMT B results. Accordingly, the results do not suggest in favor to our staged third hypothesis.

There was a statistically significant difference in stride length between patients after stroke with and without cognitive impairment ($p < .05$). Persons without cognitive impairment, on average, have significantly longer step from persons with cognitive impairment. There is also a difference in the gait speed and frequency between persons with and without cognitive impairment after stroke. Persons without cognitive impairment have faster gait and larger gait frequency, statistical value ($p < .05$).

People with a large number of categories and a smaller number of perseveration errors on the WCST test, have a higher degree of functional independence in self-care and socialization.

Table 20. Tabulation of the results of the prediction to achieve functional independence in self-care and socialization based on indicator of planned behavior of patients after stroke

Variable	Coef.	Rc	Rc ² (%)
Self-care	.133	.565	31.9
Socialization	.931	.993	98.60
Rc ²			37.6
Number of categories WCST	.799	.989	97.8
Number of perseveration errors WCST	-.241	-.872	76.0

Legend: WCST – Wisconsin Card Sorting Test; Coef-standardized coefficient of canonic function; Rc – structural coefficient; Rc² - squared structural coefficient.

Man-Whitney test results showed a statistically significant difference in the following subscales of FIM test between persons after stroke with and without cognitive impairment:

self-care, sphincter control and locomotion. It was also found that patients without cognitive impairment achieved on average significantly higher scores on the subscales of communication and socialization than patients with cognitive impairment, the differences were statistically significant at $p < .05$.

Table 21. Tabulation of statistical significance of differences in the results of all investigated areas using the FIM test in the group of patients after stroke with and without cognitive impairment

Subscale	Persons after stroke without cognitive impairment	Persons after stroke with cognitive impairment	U	r
	Средњи ранг	Средњи ранг		
<i>Area</i>				
Self-care	33.64	23.21	125.00 *	.21
Sphincter control	29.68	24.32	168.50 *	.11
Locomotion	33.00	23.38	132.00 *	.19
Comunication	38.36	21.87	73.00 *	.33
Socialization	38.73	21.77	69.00 *	.34

Legend: U – Mann-Whitney U statistic; r- effect size; * $p < .05$.

DISCUSSION

Cognitive deficits such as attention deficit disorder, reduced efficiency of control functions, memory disorders and reduction of sensory-perceptual capabilities are common lasting effects of stroke. By using neuropsychological tests it can be identified even the most subtle cognitive impairment. Thus one can get a neuropsychological profile of patients after a stroke, with its strengths and weaknesses, and so we have a baseline of his mental competence, which may be of importance for inclusion in the medical rehabilitation. Whether and in what respect are assessed cognitive skills, motor skills and functional independence of patients after stroke and patients without neurological damage, we will follow the discussion through the results of our research.

Taking into account the functional organization of the frontal lobes responsible for the ability of organizing activity, often puts emphasis on the function of self-awareness. The highest level of functioning of the frontal lobes is comparable with metacognition, or awareness of one's own knowledge and ways of using it. In the case of frontal lesions it may be discussed the inability to use preserved knowledge about their own condition in order to control behavior, which may be manifested in impossibility of self-assessment and their own problems, to grasp their consequences and making appropriate decisions (Ocić, 1988). This fact is of great importance in the process of enrolling patients in medical rehabilitation as well as for the course of rehabilitation, until achieving the elementary level of functional capability. More research has studied the relationship between executive functions (EF) and the ability to walk.

In InChanti study (Seligmann et al., 2008), which treated 900 nondemented elderly (mean age 74.6 years and cognitive performance MMSE 25.5), visual-motor time-restricted test with dimensions of cognitive flexibility, the authors came to the conclusion that the low efficiency of executive functions was correlated with a decrease in walking speed on the track with obstacles. Similar findings were obtained by (Holtzer et al., 2006), they also talk about the connection between cognitive aspects and walking speed. These authors suggest that the pace of the elderly persons is complex task that requires a higher executive control of data processing and storage.

Another study (Hausdorff et al., 2005), on the basis of these results, we can conclude that more accurate walking with greater speed were correlated with the performance of other complex motor tasks. Also, the results of these InChanti studies suggest that association of executive functions to the walking increases as the complexity of the task increases. Most authors agree that the reduced efficiency of executive functions may participate in reducing the ability to move, but reason is not defined. Neurological patients have particular difficulty when executing another task while walking. Cognitive and motor tasks simultaneously given, question the ability of the locomotional system to perform a function of walking (Seligmann et al., 2008). Many studies show that there is a connection between executive function and functional recovery after stroke in patients who have been tested and have been involved in the rehabilitation process, but the results did not show that functional recovery of patients can be predicted based on the quality of executive functions (Nyhus, Barcelo, 2009). The results of this study are comparable with the above results of previous research while complementing them with new facts emerged from the results. A small number of categories achieved in favor of a reduced ability to specify a strategy that will perform a certain activity, and therefore difficult will be the ability of self-correction, as well as changes in the behavior of certain sequences that do not produce results. Although not covered by statistical analysis, it is worth noting that most of patients after stroke has quit the ongoing set. The reasons may be manifold, the most frequently mentioned as attention deficit, lack of concentration and motivation for cooperation. In patients after stroke, among others, number of attempts to achieve the first category was recorded, which just shows that they need more time to discover the actual principle of solving the task, or an appropriate strategy for carrying out certain actions (Table 4). Similarly, a small number of achieved categories is correlated with a large number of attempts to achieve the first category, as well as frequently giving up the current set, and a large number of perseverative response (dysexecutive syndrome characteristics). The results of this research the assessed executive functions in patients after stroke are consistent with the description of behavioral disorder caused by damage to the frontal lobes defined by Lezak 's (Lezak. 2004), describing them as difficulties in initiating actions, the decline of spontaneity, loss of initiative, perseveration and rigidity, difficulty in altering mental set, problems stopping certain sequences of complex activities, with symptoms of disinhibition and impulsivity and the inability to understand their own role in the social situation (Lezak, 2004). Qualitative description, recorded during the evaluation of the test subjects after stroke in our study, fully corresponds to the above mentioned facts that qualify the status of dysfunction in executive functions. Negative response to the feedback that requires retrial, destabilize patients and usually results in a waiver of further participation in the assessment. There is a significant latency between each response and the need for constant encouragement from the outside. If we take into account the results of a large number of previous studies, we find that the leading feature cognitive deficits in

cerebrovascular diseases, is in fact the presence of defects in executive functions (Galluzzi et al., 2005; Garett et al., 2004; Saschdev et al., 2004). The results of our study show that patients after stroke manifest problem with capacity planning and organizing activities, exhibit low efficiency in defining strategies that will be implemented intentions and achieved the objective. This is particularly important with patients after stroke, when they are in a position to independently perform certain structured, purposeful and goal-directed motor activity. What makes the problem more complex is inefficient anticipating the consideration of alternatives and affiliation, this is true for mental or motor activity and reduced efficiency of self-correction (Table 4). The results of this research related to the assessment of attention, show a significant statistical difference in achievement between the surveyed patients after stroke and surveyed individuals without neurological damage. These differences are related to the selectivity of the visual efficiency as well as visuomotor and visuoconceptual monitoring, with the monitoring of the special significance of the comparative two different conceptual sequence (Table 2). It is important to note that the efficiency of the achievements in this assess attention test (TMT A/B) affects the intellectual and educational level of the respondents, but the point is that it is very sensitive to brain damage. The results show that the tested patients after stroke had low achievement in the second part of the test that required a parallel monitoring of two different conceptual series and that in the same group of respondents is a significant difference in achievement between the first and second part of the test, which also has clinical significance. Surveyed patients after stroke, registered a large number of errors, as mistakes are punished by the total time spent, and it's one of the reasons for low efficiency. The qualitative performance of subjects with impaired frontal cortex, will characterize the harsh "shifting" of attention from one stimulus to another category (Krstic, 2011). The results of this study fit into this statement. With surveyed patients after stroke the quality of care, both in the field of tenacity, as well as in the field of vigilance disorders is manifested as significantly reduced, and therefore, the impact of distractors was undoubted and more important, distractors could be different stimuli, without any possibility of selection. Considering the very administration of a given test, which involves perceptive activity, surveyed patients after stroke with right-sided hemiparesis were reasonably less effective than the surveyed patients after stroke to perform left hemiparesis.

In left-sided hemiparesis, right hemisphere dysfunction may influence the efficiency of visuospatial capabilities, while the right-sided hemiparesis, left hemisphere dysfunction can affect motor organization and motor activity. There is a clear link between the right hemisphere, attention deficit disorders and disorders visuospatial skills (Krstic, 2011). For the interpretation of our results certainly have to take into account the important role played by the graphomotor component. Qualitatively speaking surveyed individuals without neurological damage, showed a high degree of cooperation and motivation to work and cooperate with the clear objective aimed at the successful resolution of the task. Surveyed patients after a stroke showed low tolerance to constant error correction, reduced cooperation, quitting of further activities, without a clearly defined purpose. Considering the most comprehensive theory of attention posted by Mesulam, results obtained in this study we could rely on three components of neglect. The first is component of the perceptual neglect and refers to the presence of the interfering informations from the other stimulant field. The other is the motor component, which is an obstacle to direct attention orientation (over attention) towards the neglected side (eyes, limbs of the body). The third is the motivational component, which implies some sort of neglect of the contralateral space, believing that nothing

significant can be expected (Krstic, 2011). Attention deficit disorder is not always the ultimate deficit, he can be contained in a specific visual or verbal modality and accordingly can be damaged when there are lesions of the left or right hemisphere (Lezak, 2004).

In Chanti study that examined the relationship between executive function and walking, and using assessment test employed in our study (TMT A/B), and visual-motor t and time tasks, we get a result that shows significantly more parameters compared to normative values test (Table 2). This explains the difficulties in the simultaneous performance of two or more tasks, the explanation based on the theory on how people handle the received data. The explanation is based on the theory allocation of capacity, considering that the sources of the limited capacity of attention, so performing two tasks that require attention causes poorer efficiency at least in one task. This research is consistent with the results of our research. The results of this research clearly leads us to focus our attention on observation of concept selectivity, limited capacity theory, and "levels" at which its control mechanisms function. Significantly higher values of the parameters in relation to the normative values of the test in patients after stroke and moderately higher values compared to the normative values of the surveyed individuals without neurological damage, with a statistically significant difference in achievement between groups, may indicate a problem in all three or at least one of these control concepts of attention mechanisms (Table 3). In the cognitive functions, perception, memory, and thinking are included. In accordance with the theory of information processing, perception is used for selection, admission, organization and classification of stimuli from the environment, and memory provides encoding and storage tankers of received information. Conceptual reorganization of the acquired information through reviews, provided an adequate response in the form of language, visuospatial behavior or motor activity (Ocić, 1988). Evaluation of cognitive functions comprising level and quality of damage. Cognitive dysfunction can manifest in the form of measurable disturbances in various activities.

In patients with mild stroke can cause subtle language disorders, visuospatial and motor activity. Results of patients after stroke, indicating that two-thirds of patients after stroke had mild cognitive impairment (Table 6), were not unexpected, given that it was hemiparesis and not hemiplegia, which is certainly more difficult clinical condition. This enabled the efficient evaluation of executive functions so that the results obtained which refer to the executive function, are not masked by image of severe cognitive impairment. Within this research, within the group of subjects after stroke, we analyzed the relationship between the level of cognitive impairment and the evaluated parameters walk. The results show that people after stroke with the present cognitive impairment have a lower rate of walking, lower frequency and shorter walking stride length than persons with stroke without cognitive impairment (Table 19). In contrast to the cognitive functions, it is much more difficult to estimate the executive function. Executive functions correspond to the capacity of voluntary activities, or the initiation, planning, self-control and the effective implementation of the various activities (Ocić, 1988). Reduced efficiency of executive functions is expressed through qualitative aspects of behavior. It is believed that the disorders of the executive functions are often present in patients after stroke.

Since the statistical significance we got in assessed relation to cognitive impairment and walk parameters in a group of patients after stroke, depending on the severity of cognitive impairment, the results of assessed relations of executive functions and walk parameters (Table 15), with the same group of respondents allocate executive functions as a separate entity that includes cognitive impairment in itself. The data we obtained using available

literature in a given area for the purpose of comparative analysis, that support the results of our research also suggests that the restrictions may arise from executive dysfunction, requiring new procedural requirements and adjustments in the implementation of medical rehabilitation, in order to increase its efficiency and achieve optimal level of functional independence. Of course, the benefits will be those patients after stroke which no or mild cognitive impairment. Normally, walk is the automatic activity, so long as it performs no attention is paid to the sequence of execution. Give willingly walk, and centers in the CNS responsible for the scheme of walking in humans assume this role.

When damage occurs to these centers, or their routes, these schemes are no longer present, and the individual has to adapt to new circumstances and use schemes available to him. In the case of patients with hemiplegia and hemiparesis, usually it is about pathological or abnormal modified schemes (movement patterns). Kinematic and kinetic aspects of locomotion in these patients vary depending on the severity of the damage, the degree of recovery and the use of various compensatory mechanisms (Pavlovic, 2006). In support of this claim go the results obtained within the framework of a functional assay developments in the field of analysis of spatial and temporal parameters of walking (Table 7). From the results obtained from the evaluation of walk frequency can be seen statistically significant difference in achievement between the surveyed patients after stroke and patients without neurological damage (Table 9). Most respondents had a frequency of walking under the normative values of the percentage representation of 88-92%, within the norms percentages were varied from 8-12%, none of the participants in both groups had a higher frequency of walking from normative values. The reason for slightly lower efficacy in stroke frequency recorded by the patients without neurological damage can be attributed to comorbidity and age. In our most abundant sample examined comorbidity (surveyed in post-stroke patients) was 50% with hypertension, and diabetes mellitus has been represented with 36% (Table 1), the presence of degenerative diseases also not negligible. The results of research that evaluated the frequency of walking in patients with right-sided and left-sided hemiparesis not talk about statistically significant differences achievement as an explanation for the effectiveness of gait parameters can not seek in the lateralization of motor function. However, the results that follow and are related to walking speed (Table 11), and stride length (Table 12), show a statistically significant difference in achievement between the surveyed patients after stroke and patients without neurological damage. Walking speed influences the kinematics, the usual normal walking speed on level ground is 82 m / min. (males have more rapid 86 m / min, women slightly slower 77 m / min). However, the proportion of time spent in different stages of the walk also varies with speed. When a faster walking lunges length increases, so that increasing the speed in proportion leads to an increase in the swing phase, and shortening phase support (Pavlovic, 2006). The results of this study, fully-fitting the above facts that link the spatial and temporal parameters during walking. Surveyed persons after stroke have a lower speed walk from normative values. It is necessary to say that there is no statistically significant difference in gait speed between patients with right-sided and left-sided hemiparesis (Table 11). Following the spatial walk parameter (length lunges), we see that the results obtained in this study indicate a difference in achievement between the surveyed people after stroke and surveyed individuals without neurological damage, as well as the difference between the normative values and the values obtained by measuring the length of stepping in patients after stroke. The person's height, as well as shoes, can affect the size of this parameter, also the width of the surface of the palm and foot progression angle, have an impact on these values.

However, the results obtained in this study does not deny the existence of these impacts, but given the extremely low values of the length of breakthroughs, not all of these factors, or individual, can be qualified as very responsible. Taking into account the results of the evaluated spatial temporal parameters are important for the function of walking, the results of our study are consistent with the facts that rely on the theory of the dynamics of the return of the lower extremities function, through the development phase of recovery ("Movement Therapy in Hemiplegia," Signe Brunnstrom, 1970), (Pavlovic, 2006), which means that the activity as a functional gait in patients after a stroke has to go through all forms of practicing motor control in a standing position on a small area of support, both in the straddle, and the stride (Pavlovic, 2006). The results of this study to assess the trends of the task that is time-limited, show that among the tested individuals after stroke only 20% had normal mobility, 40% had good mobility and 40% have a problem with the movement.

If you look at the percentage representation of movement in patients without neurological impairment in whom 94% had normal mobility, 6% had good mobility, and none of the respondents had problems in the movement, there is an obvious difference of high statistical significance. When surveyed people after stroke, there were respondents who had a risk of falling, as well as those who have requested help or support while moving (Table 14). Bearing in mind the training course in patients after stroke, it must not be overlooked fact preparations for the adoption of this function, directed primarily towards establishing stability in the lower anti-gravity positions, all the way to the stable standing and well-controlled balance and mobility with the time-compliance. Only such an approach is the basis of achieving an efficient, safe, functional and aesthetically satisfying walk (Pavlovic, 2006). One research study that examined the recovery of motor skills of patients after a stroke, came to the conclusion that the improvement in transfer capacity and balance has been seen in exercise tasks with repetition and practicing with a mobile platform, that treatments that allow the recovery of motoric functions are based on high-intensity exercise and repetition exercises of special tasks, focused on mental practice with motor images (Peter et al., 2009). In accordance with the above investigation and observing the results obtained in this study, referring to the possibility of successfully overcoming obstacles with good preservation of equilibrium and balance, surveyed individuals after a stroke had significantly worse results compared to the tested individuals without neurological damage (Table 14) but and in comparison with the normative value. Looking at the results of the surveyed people after stroke and analyzing partial achievements that are an integral part of the overall assessment of the possibilities of overcoming the obstacles, we see that they had a problem with balance, controlling the balance, so that the successful realization (ie. overcoming obstacles) come very rarely. The reason for that may be sought in small number of registered attempts, which is certainly correlated with a small number of successful implementation. When the already mentioned equilibrium and balance, while interpreting the results, it must be taken into account the factor of uncertainty and fear as the following point that makes it difficult to perform a given activity, especially if the patient mobilization hurry or when the motivating factor for the same reduced. Results of a small pilot study that aimed to examine the difference between straight-ahead and curved walking in individuals with the main issues in the movement, supporting the results of our research acquired by assessment of walking and overcoming obstacles in patients after stroke. The test course as the number eight, has been made to present the art of walking in daily life. The results show that the test course as number eight in correlation with walking speed (which is reduced), the length of steps (which are

shorter), with the control of the movement (which is increased), and the fear of falling (that is increased), all the correlations were significant (Hess et al., 2010). In patients after stroke, the following factors should not be overlooked: awareness of their own limitations, willingness to engage in therapy and premorbid personality traits. It can be seen that at an early walk before you gain stability and balance (controlled mobility), regardless of the fact that it can be a huge motivating factor for faster recovery after stroke, there is a great risk for adverse deviation and their compensation and the ultimately may lead to developmental security and lack of functional walking. Based on study of walking recovery in patients after a stroke, it was concluded that the practicing of functional walk should begin the moment the patient is in a standing position and when he receives a satisfactory degree of balance (controlled mobility), regardless of whether it is enough to overcome the swing phase of the affected foot (Pavlovic, 2006). The results of this survey are completely reliant on the above facts from the theoretical framework of the adoption of gait in patients after stroke.

Looking at the results of research speaking of motor skills related to walking function in treated subjects, we have a clear view of the interdependence and coherence of all the analyzed kinematic parameters and kinesthetic walk. This means that in the surveyed people after stroke have a low efficiency in the evaluation of the motor index of the affected lower extremity (Table 13), which affects the efficiency of the functional movement test towards its reduction, further burdening and bringing down the frequency of walking, reducing speed and the shortening stride length. As the final outcome in patients after stroke, we get a reduced efficiency in movement, difficulty in maintaining balance and equilibrium and limited ability of overcoming obstacles (Table 16). Furthermore, they would be faced with all of the above difficulties in situations of reduced efficiency of attention and when the time for completing motor activity is limited. A great part of the research study, talks about the impact and role of cognitive functions on motor recovery and achievement of functional independence, each in their own way and in their own domain. It is believed that executive functions have a stake in motor recovery, but it is not defined if they could be used to predict functional recovery of patients (Nyhus, Barcelo, 2009). Given the above research, we have focused our research on the link between executive function and functional recovery after stroke, showing separately the results from all the evaluated area (executive function, motor function, functional independence) and connecting those results with the intention of discovering and proving existing relationships between them (Table 20). Given that examined patients after stroke with right-sided hemiparesis, showed lower efficiency in planning, organizing and independently perform activities planned, according to the results of our study in which a given functions are positively correlated with functional recovery, the results might be in favor of a slower functional recovery patients with right-hand hemiparesis.

Compatible results with the results obtained in our study of 30 patients with hemiparesis, whose functional recovery was evaluated with Bartel Index - test, which according to the same, patients with left-sided hemiparesis showed significantly better recovery of function self-care, than the patients with right-hand hemiparesis. In addition to association with executive functions, which confirm the results of our research, we must not overlook the fact that the dominant handedness in the general population is 85% of right-handed type, and hence its share in the conquest of functional independence is not negligible. The results of this research provided by the evaluation of the multivariate relationship between two sets of variables, respectively between the indicators of the ability of planned behavior and movement characteristics in patients after stroke (Table 15) show a statistically significant

association. Difficulties that appear in the conceptual organization of the current detection principle in the implementation of activities, time delay or latency between each subsequent response, a number of attempts to start implementation, frequent abandonment of actual activities without a clear insight into the inefficiency, if they focus on the movement can identify the difficulties in initiating motor activity in the presence of a break between each derived motor actions, with lack of anticipation of the next motor action without a clear organization and under the present self-correction. If the basic components of executive function and its properties of the activities ability: the will, planning, premeditated and efficient execution in the presence of cognitive inhibition (Lezak, 2004), the low efficiency of one of the components can affect the ability of efficient movement. The above theoretical fact supports the results of our research that clearly supports the connectivity capabilities of planned behavior and characteristics of the movement. For example, the low awareness of the limitations, as well as the low level of voluntary dynamism can result in a risk of falling. Reduced ability to plan, could result in disorganization of the movement or ineffective action selection, which is characterized by excessive and purposeless effort without successful implementation and without achievement of targeted activities. Ability to plan, means the ability or strategy which will be used to implement intentions and achieve the target with an insight into the real circumstances, with prediction and right choice. It precedes category of formulations intentions, and it is actually the concept of behavior, determined by a purpose. It includes motivation, and insight into their own physical and mental capabilities (Krstic, 2011). Our findings are consistent with the present theoretical review, the examined patients after a stroke had difficulties to perform certain motor activities, we note, as it is important, even in situations where the estimated motor function were not with the major constraints, and therefore requested the necessary outside support, additional stimulation and verbal instructions in order to implement the planned activities. It follows that in our patients after stroke was difficult realization of independent, integrated behavior and performance of target movements. Based on the available literature and previous findings, it is generally accepted that the preservation of executive function, in general, as well as individual aspects, with a special focus on mental flexibility and planned activities may have an effect on motor activity, mobility and integrated behavior (Table 20). Since in the patients after stroke, who have had difficulty with mental flexibility, appeared identical and purposeless movements (Tabela 17), which they did not record as wrong while it was not indicated to them, we can confirm our results with the above statement. It is necessary to clarify that this is not about the appearance of involuntary movements as a result of damage to the pyramid times, but a purposeless movements resulting from difficulties in impulse control and implementation of the planned activities as a result of the low efficiency of executive functions. Reduced effectiveness of all these aspects of executive function, and motor in healthy people may lead to global sluggish, depletion of movement and motor instability (Ocić, 1989). This fact additionally supports the results of this study.

Attention can be seen as a specific example of executive functions. Posner and colleagues (Seligmann et al., 2008), see attention such as an anatomical network whose primary purpose is to influence the work of other brain networks. The same author classifies the attention on *sustained*, which refers to the ability to sustain attention on a task for a certain period of time, *selective*, which allows the reception and elimination of irrelevant information, *divided attention*, which refers to the ability to execute more than one task at the same time; *variable* refers to the rapid change of focus from one task to another. In the study of the same author

(Seligmann et al., 2008), they focused work on divided attention and come to the conclusion that this kind of attention plays an important role in the walk in assigning multiple tasks and changing situations, while the same authors argue that there are clinical implications for the risk of falling. In this study, we evaluated the relationship between attention flexibility and precision of walking in overcoming obstacles in our patients after stroke (Table 17). Flexibility of attention assessed visuo-motor task that required the subjects simultaneously monitor two different conceptual array and switch attention from one to the other, proved to be an effective low. If we could rely on the research of mentioned author, we could define obtained result as weakness in the functioning of the domain variables of attention. It is quite justified in completely healthy people, that when locating a barrier during the walk, they are focusing attention on existing obstacles and overcoming the same, so that at any given moment ignore accuracy in walk (Table 16). The results of our study do not support fully this fact. If we again rely on the above research, the results of this study in patients after stroke, suggesting that they had a good divided attention, but not enough efficient variable attention, and therefore when overcoming obstacles, they had a number of attempts, but many smaller number of successfully implemented, while not neglecting precision during performing activities. If walking is automatic activity and requires no attention, then simultaneously performing additional tasks should not affect the accuracy and speed in the walk, or execution of another task (Hausdorff et al., 2005). Patients walk after stroke is controlled and complex task and has its own characteristics and limitations, so that can not overlook the role of attention during normal walking and walking with obstacles. It is believed that if the source of the limited capacity attention, that is why performing two tasks that require attention cause deterioration, or reduced efficacy in at least one of the tasks. However, when the time between two or more stimuli decreased, the processing time and the implementation of activities will be increased. This theory assumes that it is possible to assign a voluntary capacity to one of the stimuli, or a particular task, even when both tasks disciplined and mostly automatic (Seligmann et al., 2008). This study supports the results of our research, which shows that the evaluated patients after a stroke, will be not focused only on the obstacles, but also the accuracy of the walk, which means that they failed to give priority to one of the activities in terms of increasing the capacity of attention on a chosen activity. Effects of the twin tasks on walking, have been studied in various populations, including healthy young and older adults, as well as patients suffering from neurological diseases. Summing up the results of the given study, it was concluded that the second set task affects walking. Among healthy adults, dual tasks are often caused a decline in the performance of another task. In the case of cognitive and motor task, preference is given to the implementation of cognitive tasks. Within motor task, the problem is most prevalent in walking, a walking speed actually, because it is most vulnerable, at the multiple motor tasks (Table 19). With aging, the presence of such a neurological disease, leads to structural changes in the brain, particularly in the prefrontal area, parts of which are connected with the executive functions and focus systems. Woollacott & Shumway-Cook (Seligmann et al., 2008) based on the results of a number of studies, also concluded that the performance of cognitive tasks during walking, may increase the time of realization of the cognitive task and affect the speed of walking in terms of its reduction, but other changes of a gait pattern were not observed. Another research study, which shows the importance of multiple tasks during walking (Holtzer et al., 2006), is compatible with the aforementioned theory that during walking and performing a cognitive task, there may be changes on the walk, but if you have

multiple tasks from the same or -similar domain, and using the same population of neurons, they will not interfere with one another. Neuroimaging studies (eg, PET, IMRI), showed that during active twin tasks, activity in the prefrontal cortex highlighted, including the inferior frontal gyrus, which is not surprising, as these fields are attributed to executive function. This study confirms the results of this study, because the accuracy and overcoming obstacles during walking, are dual tasks in the same frame, and therefore were not of great mutual influence.

Lundin-Olsson (Hausdorff et al., 2005), in a small study, based on the obtained results, have found that older people who can not at the same time to "walk and talk" fall at the end, while those subjects who can, have far less prone to possible future failures. Springer (Hausdorff et al., 2005), believes that people who fall in idiopathic reasons, increasing variability walk in performing cognitive tasks during walking, while the control group consisted of those who are not prone to fall, did not vary in walking. It is interesting that it is double tasking that connected with the poor showing in tests of attention and executive functions. Faulkner (Seligmann et al., 2008) in a study of 377 elderly subjects, observed that the execution of the double tasks and reaction time associated with the risk of falling. By analyzing the results, they came to the conclusion that minimize the risk of falling in high-risk individuals such as patients after a stroke, can be prevented by reducing the requirements in one of the tasks. Although there are differences in the applied and observed responses in the realization of the double task, the general conclusion is that walking is using attention and effort involved in the double task generally increased as gait becomes less automatic, especially in patients after stroke. Effects of the dual assigning tasks on movements in patients after stroke who have walking impairment due to both (and motor and cognitive deficits) are important, especially when the patient should be involved in the process of medical rehabilitation. The results of this study of patients with post-stroke, suggesting that the movement did not slow down, and that they did not decrease the speed when communicating with the environment (Table 18). Evaluating the relationship between the two sets of variables, and between the indicators of the ability of organizing activity and attention and movement characteristics (Table 17), we found a causal relationship, which means that the low efficiency of the first set of variables, causes low efficiency of the second set of variables. Patients who survive a stroke are experiencing varying degrees of motor and neuropsychological deficiencies.

Although these deficiencies are treated as separate entities in cognitive and medical rehabilitation, there is considerable interaction between them. Certain cognitive functions will not interfere with motor skills, in terms of inhibition or stimulation. The results of this study, supported by an indisputable fact, that in the process of motor recovery, particularly in of mobilization and walking (Table 14), verbal instructions and verbal stimulation are significant, which confirms the fact that communication with the patient is not distracting but stimulating factor. Effects of communication with patients after a stroke, during the walk, are positive and reflected in the achievement of basic safety, resulting in a winning features independent walking and reaching a satisfactory level of operational independence. In addition to the results obtained in our research, came the results of a Dutch research study done on a total of 102 stroke patients in four rehabilitation centers in the Netherlands, and studied the gait, speed walking, general trends in society and came to the conclusion that the walking with company is relevant factor, and of importance for the recovery course of stroke.

Walking in the company had a surprisingly positive effect not only on the speed of walking, but also to maintain balance, endurance during walking, and the use of mobility aids.

Great care was taken in this study is devoted to assess the multivariate relationships between the following variables: indicator of planned behavior ability and the functional independence of patients after a stroke. The results of research show that the tested patients after stroke, exhibit low efficiency in all aspects of planned, purposeful goal-directed behavior (Table 20). Low efficiency dimension additionally joining the low level of attention, especially in the domain of variability, but should not be neglected aspects of sustainability, selectivity and division. Patients after stroke express and motor and cognitive difficulties, which affect the functional training to varying degrees. The results of research studies that examined the interaction between neuropsychological and motor deficiencies (Williams et al., 2008), (Seligmann et al., 2008), suggesting that people after stroke may experience a number of activity limitations. The typical range of these restrictions applies to mobility, communication and self-care. These effects have a negative impact on the movement, but also the social and professional aspects of training. The same research study shows that some patients after stroke typically favor the cognitive function of the motor task and that only certain cognitive functions interfere with motor skills, and the intensity of the motor task will be dosed to achieve the desired motor activity. (Bloem et al., 2008); (Seligmann et al., 2008). In an attempt to detect this relationship, define and implement the process of medical rehabilitation of patients after stroke, we focused on the ability of the activity organization and attention and motor recovery walk, thinking to cognitive and motor impairment can be viewed individually but in the process of rehabilitation treat as a whole. In our group of patients after stroke, low efficiency capabilities of the activity organization exhibited by the difficulty in carrying out the given activity without stimulation and instruction, reduced impulse control, reduced insight into their own mental and motor skills, the concept of behavior is not determined by clear objectives, without being able to predict and finally through the low and independent integrated behavior, maintain and stop the movement, as well as the problem of adaptation. Functional ability is essentially a measure of the achieved level of skills in motor control. Patients after stroke, according to the results of this study did not exceed the limits of their capabilities, among other things because they were unable to assess their ability to limit movement (Table 20). With stimulation, support, verbal encouragement, and instructions of another person, they managed, and the extent of actual motor activity was much higher. The research results also show that this kind of help, in most of the people after a stroke, when they are expected independence, is not reduced. Legitimate need for such help and support was no longer necessary, but the evaluated patients after stroke in our research, managed to free themselves and rely on the approved motor skills. Particularly manifested in those patients after stroke with low effective cognitive abilities. Reduced efficiency capacity planning and organizing activities with all the elements that make up its clinical correlate including low cognitive efficiency are associated with difficulties in communication, socialization and independent functioning (Table 21).

The results of this research show the correlation between the ability of planned behavior and motor skills in patients after stroke, but does not indicate that the effectiveness of the ability of planned behavior can affect the quality of motor recovery in these patients. For the possibility of proving a given impact, it would be necessary to supplement the used battery of tests for the evaluation of this variable and include a larger number of subjects.

Therefore, guided by experienced professionals who have dealt with this problem by monitoring and clinical characteristics of mental competence and motor functioning, with the results of this study, we have opened additional possibilities for a new comprehensive research that would contribute to the understanding of the theoretical aspects of this problem and create the possibility of implementing in therapeutic framework.

CONCLUSION

Based on the results obtained from conducted research, we can conclude that there is a correlation between levels of functioning ability of the activity organization, attention, and motor ability in our patients after stroke. There was also a difference in the level of functioning ability of the activity organization, attention, motor skills with all gait parameters and functional independence among surveyed patients after stroke and surveyed individuals without neurological damage.

It was found that the tested patients after stroke with cognitive impairment, have a lower walking speed, lower frequency and shorter walking stride length than the surveyed patients after stroke without cognitive impairment. It has been found that in patients after stroke in which is recorded the low efficiency in the ability of the planned behavior, ie low efficiency in executive functioning, there is a reduced internal power for movement, and the movement is less manifest. Patients after stroke with low effective attention, slowing movement and losing precision on the gait. It also confirmed the connection between quality of certain aspects of independent behavior, socialization, communication, and locomotion with the quality of executive functions.

ABSTRACT

Language impairments are frequent in stroke, especially in the hyper acute phase, occurring in 15 to 50% of stroke patients. Recovery from aphasia remains difficult to predict. Language impairment still exists in at least 50% of initially aphasic patients one year after stroke. Post-stroke aphasia is a major source of disability that can lead to impaired communication, reduced social activities, depression and a decreased likelihood of resuming work. The role of the stroke unit in improving morbidity, mortality and recovery has been clearly demonstrated. Nevertheless, the need for intense and sustained acute management of aphasia in specialized stroke units remains controversial. The recent validation of a tool to rapidly screen for aphasia (LAST) after stroke allows for its early detection and management. Early detection of aphasia after stroke may improve outcomes by taking advantage of the synergy between intensive speech therapy and early neural reorganization. Daily re-evaluation will facilitate tailored rehabilitation sessions, multidisciplinary management by the stroke team, and development of educational resources for patients and their caregivers. Standardizing protocols for identifying and managing aphasia requires the co-operation and coordination of the entire stroke team, along with the daily presence of speech therapists. These considerations are crucial for patients in the stroke unit to achieve the full benefit of the management proposed in this chapter, to ultimately promote better long term functional prognosis.

INTRODUCTION

Stroke is a public health issue, representing the third leading cause of death and the first leading cause of disability in adults [1] in the western world. As the population ages, its estimated incidence of 300 to 500/100 000 is expected to increase [2]. Specialized stroke units and/or stroke teams have been created worldwide in order to provide optimized management of stroke in the hyper acute and acute stages. Recent randomized controlled trials (RCT) have proven the efficiency of specialized stroke units in reducing morbidity and mortality, and in facilitating rapid recuperation after stroke [3-6]. Aphasia is a frequent symptom of acute stroke, and a major source of disability. It incurs increased cost of care [7] and has negative economic repercussions, such as decreased return to work [8,9]. However, early intense and sustained management of aphasia in stroke units remains controversial.

We share herein our experience of the early identification and treatment of aphasia after stroke, based primarily on a neurolinguistic framework.

We further describe existing protocols and discuss the expected benefits of early management. Optimal standardization of aphasia management can be achieved in stroke units with collaboration among physicians, nurses and speech therapists, resulting in improved outcomes after stroke. Moreover, clinically-driven research in aphasia in the acute setting is feasible and essential to improving recovery and rehabilitation outcomes.

1. IMPAIRMENTS IN THE ACUTE PHASE OF STROKE: GENERALITIES

Survivors of stroke often experience multiple co-occurring impairments, such as hemiplegia [10,11] dysphagia [12, 13], incontinence [14,15] depression [16], cognitive changes [17,18], dysarthria [19,20] and/or language impairment [21,22]. Second to hemiparesis, dysphagia, dysarthria, and language impairment are the most frequent [20]. The incidence of dysphagia approximates 55% in the acute stage [12,13].

Dysarthria and language impairment are almost as frequent in the acute phase of stroke, occurring in approximatively one-third of all stroke patients. Nonetheless, these impairments are probably underestimated, particularly in the hyper acute stage, given the lack of standardized assessments and the potential for rapid recovery [21, 23-25]. Dysarthria may occur as isolated speech impairment or with concomitant aphasia. Studies have reported dysarthria to range from 8 [26] to 42% [19] and aphasia to range from 15 [24] to 41% [12] following stroke.

Inclusion of different stroke etiologies, first versus recurrent stroke patients and different methodologies likely contributes to variations in reported frequencies of language impairment.

1.1. Definitions

Stroke is usually defined as a sudden onset of signs of focal disturbance of cerebral function lasting over 24 hours [27]. Language impairment literature can relate to ischemic, intracerebral hemorrhage (ICH) or subarachnoid hemorrhage (SAH) stroke etiologies.

Among stroke subtypes, ischemic etiology is the most frequent cause of stroke, followed by ICH and then SAH [28-30]. While there is typically an abrupt onset of neurological deficit after ischemic stroke, a progressive evolution, often with considerable tissue displacement [31], can also exist after ICH [26]. In addition, there is as much as a 10 fold higher frequency of decreased level of consciousness after ICH compared to ischemic stroke [26]. Consequently, aphasia can be identified very early after ischemic stroke, while patients with ICH may require ongoing monitoring for adequate identification of its presence. After ischemic stroke, some patients may fully recover from aphasia within days of stroke onset [24], thereby warranting careful monitoring for early recovery. Aphasia and other focal neurological deficits are not generally expected to occur after SAH, except occasionally as transient signs of vasospasm [30], or after aneurysm clipping [32].

Aphasia or language impairment is defined as an acquired impairment, characterized by anomia [33] and/or other deficits in expressive or receptive language, evidenced in any modality: speaking, listening, reading, or writing [34]. We use a neurolinguistic framework to describe brain behavior relationships in the identification and management of language impairment after stroke. (Figure 1)

Figure 1. Decision-making tree in aphasic patients.

1.2. Incidence, Predictors and Phenotypes of Language Impairment

Aphasia results from injury to the dominant hemisphere, which involves the left hemisphere in right-handed patients and in 70% of left-handed patients [35,36].

CNS= Canadian Neurological Scale.; ICH=Intracerebral Haemorrhage; ISCH=Ischemic Etiology; SAH=Subarachnoid Haemorrhage

SLT=Speech Language Therapist; * first ever stroke.; (a)proportion of SAH higher than that of ICH.; (b)TIA included in ischemic category.(c)35% incidence documented at discharge, compared to 30% very early after stroke;(d)included ISCH, ICH, and undetermined etiology;(e)Excluded cerebral trauma as cause of ICH;(f)Used a cued word finding task; combined results for those with hypothermia and those with normothermia; (g)Only included patients with good premorbid activities of daily living; (h)Geriatric ward sample of older patients.

The neural network subserving language function is increasingly recognized to be a large and complex system involving regions throughout the cerebral hemisphere. The language network comprises areas of the perisylvian cortex, including the classical language areas of Broca and Wernicke: Broca's area or Brodmann's area 44 in the posterior inferior frontal gyrus innervates adjacent motor neurons subserving the mouth and larynx, and controls the output of spoken language; Wernicke's area or Brodmann's area 22, comprising the posterior two-thirds of the superior temporal gyrus, receives information from the auditory cortex and accesses a network of cortical associations to assign word meanings; the angular gyrus in the inferior parietal lobule is adjacent to visual receptive areas and subserves the perception of written language, as well as other language processing functions. Additional regions have a significant contribution to language function: the insula, several frontal and temporal lobe regions and vast regions of the temporal, occipital, and parietal cortex, as well as subcortical nuclei. [37-42]

Figure 2. Classification of aphasia subtypes according to stroke etiologies by study. Total percentages may not equal one hundred, due to rounding to the nearest percent.

The incidence of aphasia may differ according to stroke etiology (see table 1). Some studies have documented aphasia in unselected stroke samples, involving all three etiologies: ischemic, ICH and SAH, with frequencies ranging between 21% [43] and 35% [44]. Samples that considered only first-ever stroke for all three etiologies have reported frequencies ranging from 17 [45] to 30% [46]. When SAH was excluded, studies have reported frequencies ranging from 23 [43] to 41% [12]. To our knowledge, only two studies have included both types of hemorrhagic stroke, reporting a combined frequency of 9% [43] and 20% [47]. After isolated ICH, the reported frequency of aphasia ranges from 15 [48] to 36% [12]. Two studies have reported aphasia frequencies of 3 [12] and 12% [31] after SAH. Documents of the frequency of aphasia after ischemic stroke range from 15 [24] to 40% [12], with frequencies ranging from 23 [20] to 39% [37] after first ischemic stroke. The presence of language impairment is preferentially associated with previous stroke [12], increasing age [12,21,22,41,42] female gender [42], stroke severity [24], atrial fibrillation [21,22,49,50], cardio-embolic etiology [51]. Published reports differ concerning the frequency of

phenotypes of aphasia after stroke and there is a paucity of literature describing the clinico-radiological correlation. Croquelois and Bogousslavsky recently studied 1541 patients with aphasia in the early stages of stroke (ie within the 24 hours following onset), classifying them according to aphasic patterns, where 38% presented with expressive-receptive aphasia, 37% with expressive aphasia and 25% with receptive aphasia [52] (see figure 2). In same setting, Kumral and his colleagues described a series of 454 patients with acute aphasia in the first four weeks after stroke, identifying receptive-expressive aphasia in 60%, expressive aphasia in 22%, and receptive aphasia in 14% [30]. Two studies have described more specific phenotypes in series of consecutively admitted patients with aphasia [23, 25] (see figure 2), where one demonstrated the highest frequency for expressive-receptive aphasia [23] and the other for expressive aphasia [25]. In both studies, receptive aphasia types were least frequent [23,25]. Two additional studies have reported subtypes of aphasia in acute stroke patients following ischemic stroke and ICH, excluding SAH [43, 53]. In one of these two studies, expressive-receptive aphasia predominated [43] at 40%, while receptive aphasia was most frequent in the other [53] at 65%.

The small sample size in the latter study may account for this variation [53], when compared to the larger studies. Three studies have considered aphasia classifications after isolated etiologies. Two documented aphasia after ischemic etiology [24,43], demonstrating that expressive-receptive aphasia predominated, with frequencies of 41% [43] and 56% [24], followed by expressive aphasia with frequencies of 27% [43] and 29% [24]. Receptive aphasia was least frequent at 14% in both studies.

Hier and his colleagues also documented aphasia subtypes after intracerebral hemorrhage, demonstrating the highest frequency for receptive-expressive aphasia at 31%, followed by expressive aphasia at 27% and then receptive aphasia at 14% [43].

Discrepancies in these results are probably due to differences between the sensitivity and specificity of tools versus bedside clinical evaluation and to the timing of evaluation, as aphasia can improve rapidly shortly after the onset of stroke. To illustrate, a study involving 130 acute ischemic stroke patients with aphasia demonstrated improvement of aphasia in 46% and resolution in 21% within the first 10 days following stroke onset [24]. In addition to reporting aphasia based on subtypes in these studies, some authors noted numerous unclassifiable aphasias (25%) [23, 43] or subcortical aphasias [23]. These unclassifiable aphasias may be comprised of patients with co-occurring subtypes or they may result from the method of determining subtypes, where certain patients do not fit the study's definition of each subtype. Also, diaschisis and "penumbra phenomenon", resulting in hypoperfusion to anatomical regions associated with aphasia, are possible explanations for rapid improvement, subcortical aphasia [23] or for evolution from nonfluent to fluent aphasia [25].

1.3. Prognosis

In spite of the potential for rapid improvement, language impairment usually still affects 50% of initially aphasic patients 18 months after stroke [25,53], thereby contributing to altered quality of life beyond the aphasia itself [45]. Primary consequences may include symptoms of depression, difficulty to participating in rehabilitation, difficulty understanding therapists', social draw-back and decreased frequency of professional activities [54-56].

It is difficult to predict the outcome of aphasia, even if aphasia after hemorrhagic stroke has a better prognosis than after cerebral infarctions [57]. To the present day, only initial stroke severity (according to NIHSS) and the initial severity of aphasia have been shown to predict importance of aphasia recovery after acute ischemic stroke [24,25]. In a recent study, Maas conclude that advanced age, the presence of hypodense regions, a history of previous stroke, and sedentary activity level significantly predicted a diminished likelihood of language improvement at discharge. At 6 months of follow-up, only the prestroke mRS significantly impacted likelihood of improvement [58].

2. TOOLS FOR LANGUAGE ASSESSMENT

2.1. Available Tools

Early detection of aphasia after stroke may improve rehabilitation by taking advantage of the synergy between intensive speech therapy and early neural reorganization [59-61]. Tools capable of detecting aphasia and evaluating its severity during the acute phase of stroke might help to improve early rehabilitation and to predict outcome [62]. Standard aphasia rating scales such as the Western Aphasia Battery, the Boston Diagnostic Aphasia Evaluation (BDAE), and the Boston Naming Test are not appropriate for use during the acute phase of stroke [61,63-65]. In particular, these gold standard test batteries take too long to complete and must be administered by speech and language therapists [63-65]. Global stroke rating scales such as the National Institutes of Health Stroke Scale and the Scandinavian Stroke Scale include language items and have been developed for use in acute settings [66-71], but they do not reliably detect aphasia [62]. Several attempts have been made to develop and validate brief aphasia screening scales suitable for patients with acute stroke [72-79], but all have inherent structural limitations, including [61]: (1) inclusion of written language subtests, the results of which are influenced by hemiplegia and illiteracy [59,73-76,79]; (2) use of complex visual material inappropriate for stroke patients with neuro-visual deficits [73,74], (3) inclusion of subtests that are markedly influenced by attention/executive dysfunction [73,74]; (4) excessively lengthy administration [76]; (5) difficulties with administration or scoring [59,72,76,79]; and (6) IQ dependency [75]. Some of these scales also have poor sensitivity for the detection of aphasia and provide little information regarding measures of validity and reliability [59,76].

2.2. A Novel Tool: LAST, the Language Screening Test

Early and precise diagnosis of aphasia is necessary and justified for informed decision making, such as the use of thrombolysis and the implementation of early and individually-tailored rehabilitation. Evaluation may help to localize lesion site, prior to magnetic resonance imaging [80]. A quantitative tool is needed to document the risk or presence of aphasia and to quantify repeat evaluations. Such a tool would also permit description of aphasic patterns according to lesion localization, such as transcortical aphasia following acute border-zone infarcts [81,82]. A recent study investigated the correlation between language tasks and brain

lesions, concluding that word repetition, sentence repetition and naming best-predicted lesions in the left hemisphere lesion [83]. Counting and comprehension were also impaired in patients with brain injuries [83].

We recently developed and validated a brief language screening scale in French, the Language Screening Test (LAST) [84], to screen for risk of aphasia and to facilitate timely assessment of patients after acute stroke. We validated and documented reliability for two versions of the tool in an unselected sample of chronic and acute stroke patients, excluding SAH. The scale consists of 5 subtests: picture naming (items selected based on lexical familiarity and image evoking value), repetition (of a word and a sentence), automatic sequence (counting from 1 to 10), picture recognition (including semantic, visual and phonemic foils) and auditory commands (including 1 simple and 2 complex instructions). These subtests were chosen for their high correlation with left hemisphere lesions. Two parallel and equivalent versions of LAST (a and b) were developed to avoid a re-test effect. Each item is scored as 1 if correct and 0 if incorrect or inappropriate; The total scores range from 0 to 15, with a cut-off at 14 for the diagnosis of aphasia, as compared to the BDAE. The test is administered on a letter-sized sheet of paper (one side for the expressive index and one side for the receptive index). Administration requires fewer than three minutes. The simplicity of LAST makes it suitable for bedside administration by any health professional. The LAST is useful as a rapid and reliable screen for aphasia, with proven specificity. Given the existence of two parallel versions, a second quantification of aphasia is possible during a follow-up period.

3. RECOVERY

Speech and language therapy is assumed to be beneficial; A recent Cochrane review (2010) reported some indications of the effectiveness of SLT for people with aphasia following stroke [85]. Moreover, the authors documented results favouring intensive SLT over conventional SLT. However, there was insufficient evidence in this review to establish the effectiveness of one SLT approach over another [85].

Neural processes underlying recovery remain unknown [86]. Different factors may play a role, such as age, stroke size and location, premorbid level of education, and environmental support [63]. It has been documented that hemorrhagic strokes evolve better than ischemic strokes [57]. However, the only predictive factor of speech and language recovery following cerebral infarctions is the initial severity of stroke [24,25]. One study postulated that, as with motor recovery, improvement from aphasia is directly correlated with the initial deficiency, with an estimated recovery of 70% at 90 days post stroke onset [87]. Aphasia usually results from lesions affecting the left hemisphere in right-handed patients as well as in the majority of left-handed patients [35,36]. Cerebral plasticity and changes in neural organization interfere with the restoration of language function [88,89]. This is due to post-stroke compensation in the undamaged language areas, perilesional tissue and homologue right language areas [90]. In the setting of a very focal lesion, perilesional areas participate in recovery at the acute phase and during rehabilitation. Two different mechanisms are supposed: transient hypoperfusion of these territories (“penumbra”) and early neuronal reorganization with up regulation of these areas [91]. In larger lesions, language recovery

could implicate the right hemisphere, as demonstrated in functional imaging and neurophysiologic studies [92-94]. Homologous right-sided regions that could be implicated in the process of language recovery are the superior temporal lobe (auditory control), the inferior frontal gyrus, pre-motor areas (planning of motor actions and nonlinguistic perception of language) and the motor cortex (execution of verbal motor actions) [86,95,96]. A recent study reports the extraordinary case of a man who benefited from a pre and post stroke functional MRI (fMRI): the patient presented with a Broca's aphasia after a large ischemic infarction within the territory of the left middle cerebral artery, with almost complete recovery [96]. The fMRI shows a perilesional reorganization but no significant recruitment of the right hemisphere one year after stroke [96]. A second functional MRI study reported the dynamics of language reorganization in 14 stroke patients describing activation of perilesional areas initially (as explored at day 2) [90]. Subsequent areas of reorganization included the right homologue of Broca's area in the sub acute period (day 12 after stroke) and later the reactivation of the left language areas in the chronic phase (explored one year after onset of symptoms) [90]. These findings should be taken in account when planning rehabilitation.

4. REHABILITATION

Speech and language therapy (SLT) aims at improving communication using verbal or nonverbal treatment modalities. Recent guidelines recommend speech therapy for patients with aphasia following stroke in spite of contradictory results from a few previous studies [85,97,98]. This heterogeneity could result from unsuitable tools, large heterogeneous cohorts, initiation of intensive therapy at differing time periods following stroke [99] or different rehabilitation techniques [98,100].

Functional imaging and behavioral studies have shown that SLT can modulate neural plasticity [101]. Because inappropriate rehabilitation may interfere with reorganization of language, it should be implemented according to the aphasia classification. Therefore, semantic phonological, and/or morphosyntactic therapies should be proposed according to the initial language impairment [102, 103]. In our center, different methods of SLT are performed according to each patient's needs and type of aphasia. We suggest that therapy should be implemented on a daily basis as early after stroke onset as possible. In particular, the specific contributions of the right hemisphere, such as prosodic and rhythmic properties of language, should be targeted in therapy to favor activation of contralateral language areas [104]. Early SLT in nonverbal patients or patients with severely reduced verbal output is important in order to avoid stereotypies. In accordance with one hypothesis on the dynamics of language recovery, and to capitalize on the potential role of the right hemisphere, we practice early SLT using melodic intonation therapy (MIT) [92]. We have proposed an auditory stimulation program, using a daily music listening program in our unit (one hour of music with French lyrics for our francophone population), derived from recently reported benefits [104]. Patients are encouraged to listen to music with lyrics and to actively sing along. A recent study with clinician blinding has sought to determine the immediate effects of introducing MIT early after stroke onset in patients with Broca's aphasia [105]. The treatment group showed a significant improvement compared to the control group, supporting the benefit of using this therapy method after acute stroke [105].

Although some have argued that early speech therapy is not feasible or necessary, we contend that it is indeed feasible and paramount to optimizing recovery. Second to promoting language recovery, initiation of therapy may reassure patients and help educate caregivers. As part of the therapeutic initiative, caregivers are provided advice for supportive communication [106] and to aid in eliciting compensatory strategies from the patient. Early therapy also facilitates better communication in patient care regarding medical explanations, instructions, and interactions with other therapists and the medical team.

Contribution from the entire medical and paramedical team is essential in the treatment of aphasia. In our stroke unit, therapeutic information is discussed with nursing staff, because their frequent patient interactions are crucial for progression toward rehabilitation goals. Their numerous daily interventions with patients may play a role in increasing the intensity and functionality of speech and language objectives. Providing adequate information about aphasia to front-line health professionals and families is essential to avoid ambiguous interactions. This will promote clear explanations conducive to the reception capabilities of patients. Similar educational information and explanations are necessary for both families and caregivers to avoid misconceptions. For example, some relatives may think that a patient has incurred hearing loss, amnesia, cognitive decline or dementia, psychiatric disorders or that the patient lacks physical sensation or emotion. Unfortunately, aphasia is not well understood, and educating family members and caregivers is essential to facilitate faster and more efficient recovery on the part of patients. Families and caregivers need to be well informed about the diagnosis and potential prognosis of the aphasia. As with front-line health care workers, other health professionals, such as physiotherapists or occupational therapists are inherently implicated in language rehabilitation in the acute phase. Their actions should be verbalized in an accessible formulation, with clear articulation, and with sufficient confirmation that the patient understands the instructions. In patients who are nonverbal or who have extremely limited verbal output, compensatory strategies such as the use of pictures, gestural communication, and letter require explanation to families and caregivers to prevent communication breakdown. Associated impairments, such as anosognosia after posteriorly localized aphasia and depression after anteriorly localized aphasia require additional considerations and caregiver education from the stroke team.

5. PERSPECTIVES

Effectiveness of SLT has been shown in different studies, and tools are now available to assess aphasia in acute stroke. Randomized controlled trials are still needed to indicate the best approach to delivering speech and language therapy. This will inform indications for the optimal approach, frequency, and duration of allocation and format of SLT for specific patient groups. Fortunately, recent randomized controlled studies have been conducted in the acute stage with a particular consideration of methods of speech therapy [103,107]. Controversy from potentially contradictory results arose from methodological differences such as group size, randomization methods, and type, timing (early vs. delayed) and frequency of therapy (intensive vs. conventional) [85, 98,108]. Intensive SLT, of any type, has been shown to be beneficial according to some authors [103]. Others consider that

“intensive” and “early” SLT should be undertaken to promote early neuronal re-organization [59-61,103].

Considering different therapy types by SLTs, a recent RCT investigated the effect of “Language enrichment therapy” [107], starting at day 2 post stroke and continuing to day 21. The control group received no SLT for at least the first 21 days post stroke. At day 21, 58% of the treatment group achieved a higher score on the aphasia test battery, while 35% achieved higher scores in the control group. However, the treatment group did not maintain gains in verbal communication six months following stroke. A more recent pilot RCT evaluated daily SLT according to patient classifications of aphasia, involving linguistically driven therapeutic tasks [103]. They compared patient tailored therapy with usual care and found that patients in the treatment group had significantly higher scores on the aphasia quotient and on a functional communication measure than the usual care group. Additional RCTs are still needed to better determine the optimal type, timing and intensity of speech language therapy in the setting of acute stroke.

The validation and availability of the LAST and the recent demonstration of the feasibility of conducting RCTs in the very early stages of stroke provide the impetus for designing future randomized studies that take type, timing and intensity of SLT into account after acute stroke. In addition, use of a validated language scale, such as the LAST, in randomized trials or consecutive cohorts, could further promote research correlating acute clinical signs of aphasia with MRI, by which the efficacy of therapy for aphasia subtypes could be documented.

CONCLUSION

The early detection of aphasia after stroke is essential for reliable diagnosis in order to optimize rehabilitation. Available recent tools now allow for rapid and precise assessment of aphasia. Standard care protocols and teamwork promote best practice in the use of these tools, rendering them more efficient and effective. The implementation of such protocols involves the cooperation and coordination of both medical and paramedical personnel and the daily presence of speech therapists in stroke units. In particular, we recommend this daily presence for patients with aphasia, so that they may derive maximum benefit and the advantages of units that provide this type of standard care. Consequently, we expect that the long-term functional prognosis of these patients with aphasia will improve. Moreover, future randomized trials are essential to develop specific interventions for and to optimize SLT support.

ABSTRACT

This study conducted in 2016 aimed to update and extend the existing burden of disease calculations of the WHO for road traffic noise-attributed myocardial infarction and stroke. All analyses were limited to 24 European countries and the year 2012. The burden of road traffic noise-attributed myocardial infarction and stroke was expressed in disability-adjusted life-years (DALYs) and their corresponding monetary value. Noise exposure data on agglomerations with more than 100 000 inhabitants were elicited from the Noise Observation and Information Service for Europe. We used an updated linear risk of myocardial infarction based on eight estimates from cohort studies and newly generated linear and categorical risks of stroke. Morbidity/mortality data for acute myocardial infarction and cerebrovascular disease were extracted for 474 million Europeans. Results showed 84 772 DALYs and € 2.25 billion lost to road traffic noise-attributed myocardial infarction. The burden of stroke varied from 20 608 DALYs and € 550 million (linear trend) to 202 223 and € 5.36 billion (non-linear trend). This study reported preliminary evidence regarding the DALYs due to road traffic noise-attributed myocardial infarction and road traffic noise-attributed stroke in Europe, which were associated with considerable socio-economic burden.

1. INTRODUCTION

Cardiovascular disease is a leading morbidity and mortality cause worldwide, culpable for about 30% of all deaths, and its burden is projected to increase globally until 2020 [1]. These fatal cases are mostly due to myocardial infarction and stroke, which were fourth and fifth causes for global years of life lost in 1990, and now hold first and third places, respectively [2]. Whereas mortality rates are gradually decreasing, the number of hospitalizations due to cardiovascular disease is increasing [3]. There is also gross variation in burden of cardiovascular disease across European countries [3]. However, classical risk factors cannot fully explain the variance in cardiovascular disease risk [4-6].

Road traffic noise is now widely accepted as a cardiovascular disease risk factor. Acting as an environmental stressor, it has adverse impact on catecholamine and cortisol levels, vascular hypertonicity, endothelial dysfunction, sleep quality and metabolic homeostasis, which may ultimately lead to hypertension, myocardial infarction and stroke [7]. Noise is certainly not as prominent cardiovascular disease risk factor as some lifestyle and behavioral influences, but since individual-level interventions are clearly not sufficient to reduce the global burden of cardiovascular disease, mitigating noise exposure within cities may provide substantive benefit on ecological scale, as it will affect majority of the population.

In 2011, the WHO estimated an annual loss of 60 768 disability-adjusted life-years (DALYs) from road traffic noise-attributed ischemic heart disease in Western Europe, or approximately 1.8% of the total burden of ischemic heart disease in high-income European states in the year 2004 [8]. Such quantitative measures of burden of disease are anchor elements for environmental health policy and decision making, and for adequate resource allocation and evaluation of interventions to reduce road traffic noise exposure. These calculations, however, involved some unavoidable assumptions and uncertainties, which can now be corrected. Therefore, the present study aimed to update and extend WHO's burden of disease calculations for road traffic noise-attributed myocardial infarction and to generate estimates of the burden of road traffic noise-attributed stroke.

2. METHODS

2.1. Burden of Disease Estimation

The burden of road traffic noise-attributed myocardial infarction and stroke was expressed in DALYs, which represent "years of life lost to premature death and years lived with a disability of specified severity and duration" [9]. Our analyses draw on the accepted WHO methodology previously applied to road traffic noise and myocardial infarction [8, 10]. Since our study used official online resources and ecological data, it did not undergo ethics review by an Institutional Review Board.

The first step was to calculate population-attributable fraction (PAF) for each disease: $PAF = \{\Sigma(P_i * RR_i) - 1\} / \Sigma(P_i * RR_i)$, (Equation 1), where “ P_i ” is the proportion of the population in noise exposure category “ I ”; “ RR_i ” is the relative risk of the disease at exposure category “ I ” compared to reference level; where “ ΣP_i ” should be equal to 1.

PAF was then multiplied by the number of non-fatal cases during the year 2012, in order to determine the number of non-fatal cases attributed to road traffic noise. Next, we estimated the number of years lived with disability (YLD) due to these cases: $YLD = I * DW * D$, (Equation 2), where “ I ” is the number of non-fatal cases attributed to road traffic noise; “ DW ” is the disability weight for the respective diagnosis; and “ D ” is the duration of disability in years.

The number of years of life lost (YLL) due to the fatal cases was computed by multiplying the number of deaths by the standard life expectancy at the age at which death occurred. This was done separately for men and women, after which the total number of YLL for each gender was multiplied by PAF to get YLL attributable to road traffic noise. Finally, the number of DALYs was estimated by adding together YLL and YLD.

We extended the WHO’s methodology by assigning monetary value to these DALYs, in order to provide more straightforward and intuitive interpretation of the burden of disease. This was done by multiplying the DALYs by the gross domestic product (GDP) per capita in EU-28 for the year 2012 [11]. All data were stored into spreadsheets and analyzed with Microsoft Excel v. 2010.

2.2. Noise Exposure

Information regarding the percentage of residents of major agglomerations (> 100 000) in Europe exposed to different levels of road traffic noise in 2012 was extracted from strategic noise maps available through the most thorough source so far – the Noise Observation and Information Service for Europe (NOISE) [12]. Since the Noise Observation and Information Service for Europe does not report the number of people exposed to < 55 dB, it was estimated by subtracting the number of people in the reported categories from the total population covered in the noise maps. The noise indicator we used was the day-evening-night noise level (L_{den}). Noise maps have been prepared according to the European Noise Directive [13]. Some of EU-28 member states (e.g., Greece, Hungary, Slovakia, Slovenia, and Latvia) did not provide relevant data and were excluded from the analyses.

2.3. Risk Estimates

We assigned relative risk estimates to the midpoint of each 5-dB road traffic noise category. The risk estimates used in the WHO’s calculations [8] were generated by a polynomial function based on analytic studies (cohort and case-control) [14]. In our analyses, we wanted to provide more robust estimates; therefore, we relied only on estimates from cohort studies, which was not feasible at the time of Babisch’s first meta-analysis. Since then, new high quality evidence was published. We obtained a robust linear risk of myocardial infarction (RR per 10 dB = 1.065, 95% CI: 1.007 – 1.127), using the seven cohort risk estimates extracted by Babisch in his updated 2014 meta-analysis [15], along with the risk

estimate from a cohort study just-published at the beginning of 2016 [16]. (See Table 1) They were pooled together under the inverse variance heterogeneity estimator, a meta-analytical model which is superior to the random effects estimator used by Babisch [14]. This novel estimator favors studies with lowest probability of random error, it has a more conservative 95% CI, retains a correct coverage probability and exhibits a lesser true variance regardless of heterogeneity [17]. Vienneau et al. found in their extensive meta-analysis that the exposure-response relationship between traffic noise and myocardial infarction did not deviate significantly from linearity [18], therefore, we treated the risk of myocardial infarction as linear.

With respect to stroke, few studies have been published overall, let alone cohort studies. All studies were synthesized by Dzhambov and Dimitrova [19], who pooled six estimates (three cohort, two cross-sectional, and one ecological) yielding RR per 10 dB = 1.010 (95% CI: 0.962 – 1.061). Of note, the authors found evidence against the linearity of this exposure-response relationship and reported a polynomial approximation ($R^2 = 0.95$) of the non-linear risk, based on one ecological and three cohort estimates: $RR = 0.00066295186571 \cdot (L_{den})^2 - 0.06779154098343 \cdot (L_{den}) + 2.73847143171073$ (Equation 3). The linear and the non-linear risks of stroke were both used as alternatives in our burden of disease analysis.

Table 1. Individual cohort study risk estimates and pooled linear risk for myocardial infarction per 10 dB increase of road traffic day-evening-night noise level

Study	RR	95% CI		Weight (%)
Caerphilly-CO*	0.969	0.727	1.290	1.93
Speedwell-CO*	0.875	0.683	1.121	2.58

Road traffic noise and incident myocardial infarction: A prospective cohort study. PLoS ONE 2012; 7:1-7.

2.4. Morbidity, Mortality and Life Expectancy

Incident myocardial infarction and stroke cases (morbidity) were defined according to the International Classification for Hospital Morbidity Tabulation (ISHMT) taxonomy – ISHMT: 0903 (ICD-9: 410/ICD-10: I21-I22) for acute myocardial infarction and ISHMT: 0908 (ICD-9: 430-434, 436-438/ICD-10: I60-I69) for cerebrovascular diseases. Mortality cases were defined according to the Mortality tabulation list 1 of the ICD-10 (MLT1) – ICD-10: I21-I22 for acute myocardial infarction and MLT1: 1069 (ICD-10: I60-I69) for cerebrovascular diseases. The number of non-fatal cases was calculated by subtracting the number of deaths from the number of all discharges, to avoid double counting of cases [8]. Morbidity and mortality data for the year 2012 (or the year closest to it) within each age group (< 35, 35 – 44, 45 – 54, 55 – 64, 65 – 74, >74) and country were drawn from the European Hospital Morbidity Database [20] and the European Detailed Mortality Database [21], respectively. The average life expectancy in each age group and country for the year 2012 was obtained from the European Health and Life Expectancy Information System [22].

Some countries did not report noise exposure data, as mentioned above, whereas others had missing data on age-stratified morbidity/mortality. Therefore, the analyses excluded some EU-28 countries, and included Iceland, Norway and Switzerland, which had prepared strategic noise maps, although they are not member-states. Overall, 24 European countries were included in our analyses: Austria, Belgium, Bulgaria, Croatia, Czech Republic, Denmark, Estonia, Finland, France, Germany, Iceland, Ireland, Italy, Lithuania, Luxembourg, Malta, Netherlands, Norway, Poland, Romania, Spain, Sweden, Switzerland, and the United Kingdom.

2.5. Disability Weights and Duration of Disability

The WHO's burden of disease calculations used the disability weight (DW) for myocardial infarction from the Global Burden of Disease (GBD) 2002 [8, 23]. In our study, we selected a DW for stroke of 0.580 (range: 0.519 – 0.639), which referred to long-term consequences of severe stroke plus cognition problems; it was estimated in a sample of 30 660 people from Europe in 2013 and is representative of European countries [24]. As regards myocardial infarction, the same European study reported DW only for days 3 – 28 following acute myocardial infarction [24], whereas we were interested in days 1 – 2 [8]. Therefore, we used DW = 0.432 (range: 0.288 – 0.579), which is DW for acute myocardial infarction (days 1 – 2) prepared for the GBD 2013 study [25], by combining the GBD 2010 results with those from the 2013 European study [24, 25]. We also checked alternative sources of DWs as sensitivity analysis. (See Table 2) The average duration of disability for myocardial infarction and stroke was assumed to be one year, to calculate losses for each year of life [8].

2.6. Monetary Valuation

As previously done by other authors, the monetary value of one DALY was set at the 2012 GDP per capita in EU-28 [11]. According to Eurostat, it was € 26 500 [26].

Table 2. Alternative disability weights (DW) for myocardial infarction (MI) and stroke and corresponding disability-adjusted life-years lost to road traffic noise in 2012

Source of DW	DW (range)	DALYs (range)
Myocardial infarction:		
GBD 2004 study	0.439 (0.405 – 0.477)	84 883 (84 343 – 85 487)
European 2013 study (acute MI, 3-28 days)	0.098 (0.080 – 0.121)	79 463 (79 177 – 79 828)
GBD 2013 study (acute MI, 3-28 days)	0.074 (0.049 – 0.150)	79 082 (78 684 – 79 574)
Stroke (linear trend for risk):		
GBD 2004 study	0.266 (0.228 – 0.295)	19 002 (18 808 – 19 151)
European 2013 study (moderate stroke)	0.075 (0.059 – 0.093)	18 026 (17 944 – 18 118)
GBD 2013 (moderate stroke + cognition problems)	0.316 (0.206 – 0.437)	19 258 (18 696 – 19 877)
GBD 2013 (severe stroke + cognition problems)	0.588 (0.411 – 0.744)	20 648 (19 744 – 21 446)
Stroke (non-linear trend for risk):		
GBD 2004 study	0.266 (0.228 – 0.295)	186 471 (184 564 – 187 926)
European 2013 study (moderate stroke)	0.075 (0.059 – 0.093)	176 889 (176 086 – 177 792)
GBD 2013 (moderate stroke + cognition problems)	0.316 (0.206 – 0.437)	188 979 (183 461 – 195 049)
GBD 2013 (severe stroke + cognition problems)	0.588 (0.411 – 0.744)	202 624 (193 745 – 210 450)

3. RESULTS

Table 3 shows the distribution of people exposed to different noise bands and the corresponding relative risks for myocardial infarction and stroke. Noise exposure data were available for a total of 142 069 068 citizens within major agglomerations in the selected 24 countries. More than 60% fell into the reference category < 55 dB considered safe from the cardiovascular effects of road traffic noise. In order not to overestimate the risk of stroke, it was held constant above 70 dB. This was done because the polynomial did not cover exposure > 70 dB. There was a clear discordance between the risks yielded by the linear and non-linear risks, and this discordance was more pronounced in the higher exposure categories, reaching 2% versus 29% above 70 dB.

The source population for our morbidity analyses were 473 648 109 people aged 0 – 85+ from the 24 countries included in the study, which means that the noise exposure data covered about 30% of them. Overall, 1 714 480 discharges and 396 631 ($\approx 23\%$) deaths from cerebrovascular disease occurred in 2012, which yielded 1 317 849 non-fatal cases. There were 876 187 discharges, 236 369 deaths ($\approx 27\%$), and 639 818 non-fatal cases of acute myocardial infarction. Table 4 lists the number of deaths stratified by gender and age group, along with the corresponding life expectancies. Majority of deaths occurred in elderly people (> 65 years).

Table 3. Distribution of inhabitants across different noise categories in the European countries included in the study and corresponding relative risks of myocardial infarction and stroke

Road traffic noise exposure in 2012		Relative risk		
L_{den} [dB(A)]	Number of people exposed (%)	Myocardial infarction	Stroke	
		Linear risk	Linear risk	Non-linear risk
< 55	87 856 368 (62.84)	1.000	1.000	1.000
55 – 59	20 823 700 (14.66)	1.033	1.005	1.028
60 – 64	16 142 100 (11.36)	1.065	1.010	1.084
65 – 69	11 443 300 (8.05)	1.098	1.015	1.172
70 – 74	5 087 100 (3.58)	1.130	1.020	1.294
≥ 75	716 500 (0.50)	1.163	1.020	1.294
Population attributable fraction		0.025	0.004	0.038
Number of non-fatal cases attributed to road traffic noise		15 896	5 112	50 166

Abbreviations: L_{den} – noise level day-evening-night.

Table 4. Distribution of fatal cases of myocardial infarction and stroke and corresponding average life expectancies across sexes and age groups

Age	Men			Women

Abbreviations: MI – myocardial infarction.

Based on the risk estimates and the proportion of people exposed in each noise category, we calculated PAFs for the three disease scenarios. Depending on the trend for risk, 0.4% (5 112) to 3.8% (50 166) of the non-fatal cases of stroke could be attributed to road traffic noise; 2.5% (15 896) of the non-fatal cases of myocardial infarction were road traffic noise-related.

Total YLL due to myocardial infarction were 3 135 782 (1 895 700 for men and 1 240 081 for women), of which 77 905 (47 097 for men and 30 809 for women) were attributed to road traffic noise. Total YLL due to stroke were 4 547 971 (1 873 752 for men and 2 674 219

for women), of which 173 127 (71 328 for men and 101 799) were attributed to road traffic noise, assuming PAF = 3.8% (non-linear risk).

Table 5 shows the final burden of disease estimates. After multiplying the non-fatal cases attributed to road traffic noise by the respective DW and assuming one year as the average duration of disability, the estimated DALYs lost to road traffic noise-attributed myocardial infarction and stroke in 2012 were 84 772 (82 483 – 87 109) and 202 223 (199 163 – 205 183), respectively. Their corresponding monetary value amounted to € 2.25 (2.19 – 2.31) and € 5.36 (5.28 – 5.44) billion, respectively. The linear risk of stroke suggested subtler losses – 20 608 DALYs (20 296 – 20 909) and € 0.55 (0.54 – 0.55) billion. The number of road traffic noise-attributed DALYs we found for ischemic heart disease (12 148 292) and stroke (6 977 256) were 0.70% and 2.90%, respectively, of the total DALYs estimated in the selected countries for the year 2012 [27].

Table 5. Annual burden of disease from road traffic noise-attributed myocardial infarction and stroke in Europe

	Myocardial infarction	Stroke	
	Linear risk	Linear risk	Non-linear risk
Disability weight (range)	0.432 (0.288 – 0.579)	0.580 (0.519 – 0.639)	0.580 (0.519 – 0.639)
YLL	77 905	17 643	173 127
YLD	6 867 (4 578 – 9 204)	2 965 (2 653 – 3 267)	29 096 (26 036 – 32 056)
DALYs	84 772 (82 483 – 87 109)	20 608 (20 296 – 20 909)	202 223 (199 163 – 205 183)
Monetary valuation of DALYs in billion €	2.25 (2.19 – 2.31)	0.55 (0.54 – 0.55)	5.36 (5.28 – 5.44)

Note. YLL – years of life lost; YLD – years lived with disability; DALYs – disability-adjusted life-years.

Sensitivity analyses indicated that the alternative DWs had modest impact on the burden of disease estimates. On the other hand, applying the original third order polynomial of Babisch [14] to estimate the burden of disease from myocardial infarction decreased the PAF to 1.3% and the DALYs lost to 43 686 (42 506 – 44 890). (Data not shown.)

4. DISCUSSION

This chapter extended the WHO methodology to estimate an updated annual burden of myocardial infarction and stroke in 24 European countries. Over 84 000 DALYs and two and € 2.25 billion were lost in 2012 to road traffic noise-attributed myocardial infarction. The burden of stroke varied considerably from about 21 000 DALYs and € 550 million to over 200 000 DALYs and € 5.36 billion, depending on the type of risk used in the calculations.

To our knowledge, this is one of the first burden of disease analyses involving road traffic noise-attributed stroke, as “road traffic noise and stroke” studies are a relatively new research field. Thus, there is no apparent prior example to compare our findings to. On the other hand, comparison with the WHO Global Health Estimates [27] showed that the losses to road traffic noise-attributed stroke in 2012 were almost 3% of the total number of DALYs lost from stroke, which is quite alarming.

Conversely, the burden of road traffic noise-attributed ischemic heart disease was previously assessed by the WHO and amounted to 60 768 DALYs [8]; in other words, it was approximately 20 000 DALYs lower than what we found for myocardial infarction. There are several possible explanations of this discrepancy. First and foremost, we used an updated linear exposure-response relationship between road traffic noise and the risk of myocardial infarction – it was based on eight risk estimates from cohort studies, which made it superior to the old polynomial based on five estimates from both cohort and case-control studies [14]. That polynomial used $L_{den} < 60$ dB as the reference level, meaning that people in this category were not considered to be at risk of myocardial infarction [14]; on the other hand, we used the category < 55 dB. Our linear risk suggested higher risks than the old polynomial below 70 dB (3%, 6.5% and 10% versus 0%, 1.5% and 6.7%). Above 70 dB the case was exactly the opposite (13% and 16% versus 16% and 30%). In spite of this, the risk at lower exposure levels appears to have greater impact on the calculated PAF because only $\approx 4\%$ of all Europeans are exposed to $L_{den} > 70$ dB. As we demonstrated in the sensitivity analyses, using the old polynomial would have underestimated substantially the number of DALYs.

Another noticeable difference with Babisch's analysis is that he did not use raw morbidity/mortality data to estimate the DALYs for IHD in the EU member states, but rather multiplied PAF by the total number of DALYs for ischemic heart disease in high-income European countries [8]. This total number of DALYs was elicited from the GBD 2004 update [28], which likely introduced significant bias, because these DALYs were calculated for the year 2004, while noise exposure data from NOISE was available for 2007 and onwards [12]. Also, Babisch had to assume that "road traffic noise has the similar impact on all ischemic heart disease as on myocardial infarction", because no DALYs were reported for myocardial infarction in the Global burden of disease 2004 report [8]. This means that the number of road traffic noise-attributed DALYs he estimated reflected the burden of ischemic heart disease as a group, but overestimated the burden of myocardial infarction alone. This notion is supported by our sensitivity analysis, which showed that the estimated road traffic noise-attributed DALYs for myocardial infarction were only 0.70% of the total number of DALYs for ischemic heart disease in 2012, and not the anticipated 2.5% (based on the PAF we calculated).

Going further, both the total number of DALYs and the estimated road traffic noise-attributed DALYs in Babisch's study referred only to high-income countries (defined as those having gross national income $\geq$ \$ 10 066 in 2004), whereas the percentage of people exposed to different noise levels was derived from noise maps reported by both high- and middle-income countries [8]. Lower-income countries, however, have poorer road traffic noise control and could have biased upwards the percentage of people in high noise exposure categories. In our study, both noise exposure and morbidity/mortality data referred to the same countries. Also of note, at the time of Babisch's study, the Noise Observation and Information Service for Europe covered agglomerations with $> 250\,000$ inhabitants, while now it reports data on agglomerations with $> 100\,000$ inhabitants as well [8, 12], giving more comprehensive coverage of the population.

A 2013 study commissioned by the Directorate-General for Environment improved the WHO methodology by implemented sophisticated procedures to estimate the burden of traffic noise-attributed hypertension, ischemic heart disease, and stroke [29]. Houthuijs et al. covered the population of 33 European countries (EU-28 plus Iceland, Liechtenstein, Norway, Switzerland, and Turkey), used data from the second round of noise mapping, took into

consideration different sources of environmental noise both within and outside agglomerations, and used raw morbidity and mortality data [29]. They estimated 900 000 additional cases of hypertension in 2012, 43 000 additional annual morbidity, and 10 000 annual mortality cases due to ischemic heart disease and stroke [29]. Road traffic noise within agglomerations was associated with 17 700 hospital discharges, 66 300 YLL, and 6 170 YLD due to ischemic heart disease, and 7 380 discharges, 27 500 YLL, and 3 610 YLD due to stroke [29]. For ischemic heart disease, they used linear RR per 10 dB = 1.05, 95% CI: 1.02 – 1.09), which was based on cohort and case-control studies on both road traffic and aircraft noise and was lower than our risk (RR per 10 dB = 1.065, 95% CI: 1.007, 1.127). For stroke, they conducted an ad-hoc meta-analysis of six road traffic and aircraft noise studies, which yielded RR per 10 dB = 1.04, 95% CI: 1.00 – 1.09. This linearized risk overestimated the linear risk used in our study (RR per 10 dB = 1.010, 95% CI: 0.962 – 1.061) and greatly underestimated the non-linear risk. Despite that Houthuijs et al. covered 33 countries, and we only 24, our burden of disease estimates are greater than theirs, because our risk estimates referred only to road traffic noise and were derived from high quality studies, some of which were not published at the time of Houthuijs et al.'s analysis; we also pooled them under a superior meta-analytical estimator. Further comparison in terms of DALYs and monetary losses is not possible, since these estimates were not generated by the authors [29]. Despite the discrepancies, both our studies clearly indicate that the burden of road traffic noise is higher than previously believed despite the lower percentage of people exposed to $L_{den} > 55$ dB in 2012 in comparison to 2007 [12] and the decreasing cardiovascular disease mortality in many European countries [3]. They also demonstrate that the quality and design of primary epidemiological studies used to generate meta-relative risks has substantial impact on burden of disease estimation.

4.1. Strengths and Limitations

The present study has several limitations. The exposure-response relationship between road traffic noise and myocardial infarction was treated as linear, because its departure from linearity was previously explored and the authors did not find a higher order term to provide significant improvement [18]. Nonetheless, they found that primary studies reporting linear risk showed higher risk of myocardial infarction / ischemic heart disease as opposed to those for which it was derived from categorically reported risks [18]. Therefore, the linear trend we used might underestimate the risk and renders our results conservative, which further reinforces the conclusion that the burden of road traffic noise-related myocardial infarction has increased. Also, from meta-analytical standpoint, it is controversial whether risk estimates for men and women from the same study should be pooled together as if they came from different studies – this creates an issue of statistical dependency. However, this was done, since it is an approach used by Babisch and the WHO with the objective of deriving “a ‘best guess’ pooled relationship for the calculation of population-attributable risks” [8].

As for the risk of stroke, there is not sufficient number of prospective studies published so far to pool a stable cohort risk estimate; therefore, we used both observational and analytical studies. Dzhambov and Dimitrova [19] contended that the exposure-response relationship followed a non-linear risk, but the polynomial they reported was based only on three cohort estimates (two from the same study) and one ecological. Therefore, we also

report burden of disease analyses based on the linear risk they provided. Future meta-analyses should update this pooled risk of stroke with additional cohort studies.

The Noise Observation and Information Service for Europe covered only 30% of the total study population [12], but since it was not possible to obtain exposure data on all settlements, we had to extrapolate these data to the entire population, for which we had morbidity/mortality data. As alleged by the WHO, the impact of this approach is probably minimal, at least in Western Europe, but still could have led to some overestimation of the burden, since traffic in rural and smaller settlements is not as intensive as in major agglomerations [8].

The taxonomy we used to define acute myocardial infarction enables us to interpret the results in terms of myocardial infarction alone, and not ischemic heart disease. Conversely, although we refer to “stroke” throughout the text, the codes we used refer to the more general category of cerebrovascular disease. We extracted morbidity and mortality data on this group of diagnoses, because some of the primary studies pooled by Dzhambov and Dimitrova also defined their outcome as cerebrovascular disease [19]. Thus, although we assumed that the effect of road traffic noise on stroke is the same as on cerebrovascular disease, the burden of stroke may be somewhat overestimated.

CONCLUSION

This study updated the evidence about the burden of disease from road traffic noise in Europe and showed that, despite the reduction in noise exposure above 55 dB, the disability-adjusted life-years due to myocardial infarction are higher than expected. It also reported preliminary evidence regarding stroke, which appears to be associated with considerable socio-economic burden.

Chapter 67

STUDY OF TWO STROKE TECHNIQUES WITH TRANSVERSE MOVEMENT OF THE RIGHT HAND ON CLASSICAL GUITAR USING SURFACE EMG

***Natalia Diaz Fernández de Monge^{1,*}
and Juan Granda Vera²***

¹Professional classical guitarist

²Human Movement Analysis Research Group
University of Grenada, Spain

ABSTRACT

The purpose of this study is to examine expert playing patterns involving the index and middle fingers of the right hand of two professional classical guitar players using surface electromyographic (EMG) to analyse two different stroke techniques, rest stroke and free stroke, during the performance of a musical composition.

In the area of instrumental technique analysis, there are few studies that use EMG technology. The current study provides an empirical basis to help understand underlying motor control processes in classical guitar performance technique. Further it establishes a process for exploration of instrument technique during music performance.

Two case studies were conducted with professional guitarists who performed the classical guitar piece Estudio No. 5 by Francisco Tárrega (1993). Execution of the piece was recorded using EMG equipment and two video cameras. Subsequent analysis of the fingers involved the synchronisation of EMG data with each of the finger movements made during the performance of technically challenging sections of the music (e.g., transverse movement of the right hand or string crossing).

Results indicated a high degree of stability and consistency in terms of muscular activation, which demonstrated the excellent motor control of the expert guitarists. It is important to note that, each performer showed consistent patterns of motor control for each of the two repetitions of the musical passage even though a comparison of the two performers reveals different surface EMG patterns. These results indicate a measure of

* Corresponding Author's Email: ndfdm@hotmail.com.

technique individualization during the performance of the technically challenging section (transverse movement or string crossing) for the fingers (index and middle) and strokes (rest stroke and free stroke).

Keywords: Music performance, instrumental technique, guitar, surface EMG, rest stroke, free stroke

INTRODUCTION

Technical skills are required to perform any musical piece correctly. Expert-level technique serves to free the interpreter from physical constraints in order to allow for greater freedom of musical expression. Thus, technique should be considered a creative element instead of an end unto itself. It is a means of gaining confidence and control, and, through this, magnifying musical effects and improving performance outcomes (Deschaussées, 2002).

Typically, different master teachers have varying approaches to teaching guitar technique, resulting in considerable motor control differences, especially for right hand stroke techniques. Russell (1993) states that although the left hand movements of most advanced guitarists are generally standardised and some diversity exists in terms of different fingerings which may be used to reduce difficulty or for different musical preferences, there are considerable differences in the way the right hand is used. Each performer tends to adopt a personalized posture and technique. However, when discussing technique it is common to refer to the type of positioning of the hands, while what is truly and fundamentally important lies in coordinating multiple seemingly insignificant movements.

Consequently, based on this, successful execution on the guitar can be accomplished in many ways and strings can be plucked in a variety of different manners. Decision-making with regard to the kind of stroke to employ is a primary methodological resource in teaching the instrument. Further, the manner in which a stroke is executed provides the means to develop proper technique and to facilitate the interpretation of musical compositions from different eras and styles. The two methods of plucking the string are: 1) the rest stroke, which involves resting the finger on the neighbouring string after a finger plucks a string, and 2) the free stroke, in which the finger does not rest anywhere, the finger only flexes (De Contreras, 1998; Duncan, 1980; Pujol, 1956; Schneider, 1985).

In general, musical technique and interpretation are founded on teaching methods governed by tradition and pedagogy which are commonly determined by the teacher's own artistic preferences (Visentin and Shan, 2011). In accordance with this, it is noteworthy that current pedagogical methods, which substantively focus on learning technique, are normally based on a series of practical tips which are either generally accepted because they are based on common sense or they have been proposed by teachers of recognised prestige. This reality and the small number of existing empirical studies on guitar technique underscore the relevance of the current study. The results of the study contribute objective information about how to play the guitar and motor control characteristics during performance.

In the field of guitar, one study comparing plucking techniques which did not employ EMG was conducted by Marques, Rosset-Llobet, Fonseca Marques, Gurgel and Augusto (2003). The study indicated rest stroke technique to primarily involve flexion and extension of the proximal phalanges of the three middle fingers. This distinguishes it from the free

stroke technique, which involved incomplete flexion of the middle phalanges of the same digits. One of the conclusions reached by the authors was that rest stroke technique requires greater tension of the flexor muscles, because, after plucking a string, the finger then rests on the neighbouring string.

An additional study of classical guitar plucking techniques (rest stroke and free stroke) conducted by Granda, Barbero and Diaz (2006) examined the degree of muscle involvement using EMG recording for both expert and novice players. The results of the study showed differences in EMG activity between the index and middle fingers of the right hand and significant differences in muscle voltage levels between novices and experts.

In continuation to the work above, Granda, Barbero and Diaz (2007) conducted a study with guitar students at the Professional Music Conservatory of Melilla which determined levels of muscle voltage using surface EMG recording of the right hand. The rest stroke method was confirmed to involve lower levels of muscle voltage, allowing for better development at the beginner and intermediate guitar technique levels, both in terms of skill acquisition and retention.

EMG has also enabled researchers to examine specific techniques used with musical instruments other than the guitar. For example, Bejjani, Ferrara, Xu, Tomaino, Pavlidis, Wu, and Dommerholt (1989) published a research paper which compared three different techniques for playing the piano, confirming the utility of EMG as a means of distinguishing muscle activity for each of the techniques. The results of a study by Moore (1992) on the execution of trills on the piano showed that finger acceleration and EMG activity are presented as phases characteristic of the trill cycle. Furthermore, magnitude and coordination are dependent on speed of the execution of the trill, the dynamic level, and place where the finger hits the key. Another study with professional pianists to complement teaching techniques for piano was conducted by Montes, Bedmar and Sol Martin (1993). The study examined changes in EMG activity by measuring the short abductor muscle of the thumb. The results were used for continued study of the various execution techniques for this instrument. In the same vein, a study examining alternatives to help improve the quality of piano teaching was conducted by Granda, Barbero and Rodriguez (2004). Their results indicated that implementing a program based on information limitation appears to provide significant improvement in the motor control of hand actions, which results in a decreased voltage levels in the thumb extensor muscle and increased values for the little finger extensor, supported by kinaesthetic and proprioceptive information processes.

In terms of bowed string instrument technique, Moore, Hary and Naill (1988) analysed trills executed on the cello to determine the characteristics and speed of finger movement as these relate to the EMG activity of the muscles that control them, providing information for potential biofeedback studies on problems related to instrument practice. Although Fjellman-Wiklund, Grip, Karlsson and Sundelin (2004) used EMG as a measuring instrument to study disorders related to playing stringed instruments, their study showed that EMG can be used to analyse individual differences in the performance of a musical piece and to evaluate different methods of action. And lastly, the aim of the study conducted by Granda, Barbero and Rodriguez (2010) was to analyse and describe the kinematic patterns of the right arm and muscle voltage levels of the anterior deltoid muscles, finger flexors and extensor pollicis of a professional and highly proficient cellist during the interpretation of different sections of a piece of music. Their study demonstrated a stable movement pattern during the performance of a musical piece, and also showed variation in the kinematic values and muscle activity of

the arm segments studied, which were offset by adjustments in other segments of the arm. Another important finding of the study was the fact that the driving force for the right arm in a cellist's technique was the shoulder. The hand and fingers act to correct and absorb shock from the general movements stemming from the shoulder.

Using the abovementioned research as a foundation, the current research aims to determine muscle voltage levels through surface EMG recording during the performance of a musical piece by two highly proficient professional guitarists for two different stroke techniques in order to describe and analyse motor control patterns used in guitar performance which are the result of attaining expertise in the execution of motor skills for both plucking methods.

METHOD

This study took the form of a case study experimental design with a single post-test. Each participant was considered a unique case, since the aim was to gain insight into the participants' performance behaviours (the patterns of activity of each participant) and to investigate possible intra-subject differences.

In the first phase of the experiment, an expert with over 40 years of experience as a teacher and more than 25 years dedicated to musical interpretation was asked what classical guitar piece would be most suitable for the study.

By this process, *Estudio No. 5* by Francisco Tárrega (1993) was selected for the test protocol. The participants were then asked if they agreed that the piece would be useful for studying both right hand plucking techniques (rest stroke and free stroke) using the index and middle fingers.

This was necessary because, for many compositions, there can be a variety left and right hand fingering and plucking patterns. The participants agreed as to the appropriateness of the selected composition.

During this phase, two guitar virtuosos (experienced professionals) were asked to practice the aforementioned *Estudio* using both stroke techniques (rest stroke and free stroke) for 16 minutes a day (8 minutes of rest stroke practice, and 8 minutes of free-stroke practice) over the period of one month. They were also asked to take extreme care to keep their fingernails in optimum condition during their practice so that they would be in excellent condition on the day when the data was to be recorded.

In the second phase, data were collected on the levels of muscle activity and finger actions. Prior to starting the experiment, all participants performed warm-up exercises, basically consisting of scales and passages from the *Estudio*. They were told to take as much time as they needed to warm up, to ensure they were fully prepared to perform the test piece. In the data recording session, each guitarist played the *Estudio* 4 times: 2 times with the rest stroke technique and 2 times with the free stroke technique, starting with the technique each preferred (see Figure 1).

	Repetition 1	Repetition 2	Repetition 3	Repetition 4
Interpreter 1	Free stroke	Rest stroke	Free stroke	Rest stroke
Interpreter 2	Rest stroke	Free stroke	Rest stroke	Free stroke

Figure 1. Order in which each of the guitarists interpreted the piece.

The guitarists interpreted the piece from memory in each of the four repetitions, and in each repetition the guitarists employed the same fingerings for the left and right hands. All of the soloists' performances were recorded using EMG equipment and two digital cameras. Surface EMG measurements were taken using the I-330 12-channel recording system (4 EMG), (J & J Engineering). Bipolar EMG recordings of extrinsic finger flexors were obtained using pairs of Ag-AgCl surface electrodes. EMG signals from the flexors of each finger were recorded on an ASUS F3J model laptop. Two Casio EXF1 digital cameras recording at 100 frames per second were used to record video and audio of the interpretation. These were positioned to facilitate subsequent analysis of the fingers involved in the study, the index and middle fingers, and for synchronisation of EMG data with each one of the moments (actions) of the fingers during the performance.

For surface EMG recording, electrodes were placed in accordance with the recommendations of Basmajian and Blumenstein (1989). Two pairs of electrodes were placed parallelly and longitudinally from the proximal to the distal insertion, so that each pair recorded tension generated by the actions of each of the fingers studied, with each compartment separated by 13 mm, the distance recommended by Shan and Visentin (2005) to avoid the cross-talk effect between the segments of muscle studied. This placement of surface electrodes did not allow the activity of the FDS finger superficial flexor to be separated from the FDP finger deep flexor. However, as force was applied in the distal phalanges of the finger position studied the deep flexor FDP was the main contributor to finger forces (Li, Zatsiorsky and Latash, 2000). The reference ground electrode was placed on the dorsal side of the forearm. All the EMG signals were sampled at 100 hertz, amplified, and then filtered using a high-pass filter at 10 hertz and a low-pass filter at 500 hertz, effectively resulting in band pass data of 10-500 hertz.

Each pair of electrodes recorded voltage generated by the muscles needed to produce the actions of each of the fingers studied. This allowed the researchers to verify the relationship between finger placement and muscle activity in order to analyse the motor control patterns of the finger segments. To ensure the validity and reliability of data recording, the activity of each finger was sampled separately with EMG recording software. The level of activation of performing fingers was verified, while the fingers which remained inactive showed minimum and unchanged tension.

For data analysis, a section of the Estudio was selected (Figure 2). In this passage, performers only use the index and middle fingers of the right hand. This section presented a series of relevant guitar technique challenges to be used in subsequent study of the action of the fingers which are the primary object of this study. The results for the technically

challenging section selected correspond to transverse displacement of the fingers of the right hand, i.e., string crossing.

Figure 2. Selected passage (measures 3 to 7) of Estudio No. 5 by Francisco Tárrega (1993).

For the analysis of surface EMG measurements, the data collected was first synchronised with the videos recorded of the participants' performance using EMG recording software. Post-synchronisation, the videos were viewed to identify precisely which situations corresponded to the musical passages that were the focus of the study. Using this process, sections of EMG data that matched these video segments were then identified.

After extracting the audio-video recordings and the EMG for the identified musical passages, each section was viewed frame by frame in order to precisely and rigorously determine the EMG value for each moment of finger control during the execution of the stroke, providing the information that would later be used for analysis and interpretation of emergent behaviours in each situation analysed.

RESULTS AND DISCUSSION

Surface EMG patterns for the index and middle fingers and the technique employed (rest stroke or free stroke) in each case are indicated below for some of the musical segments analysed. In each instance, the guitarists were performing a transverse hand movement, i.e., moving the fingers from one string to another laterally across the fret board. Transverse right hand movement requires correct left hand finger posture and therefore presents a technical challenge which is practiced from the initial stages of studying the instrument (Carlevaro, 1979).

Participant 1

As illustrated in Figure 3, during the execution of identified technical passage using the rest stroke technique, the guitarist (participant 1) changed from the first string plucked with the middle finger to the second which was plucked with the index finger. When the second string is plucked, a minimal rise in voltage is observed which decreases as the index finger action ends and comes to rest on the neighbouring string. The higher voltage levels attained in the action of the plucking finger is the result of the intensity with which the guitarist executes this moment of the interpretation, in accordance with the requirements of the piece. In this same vein, in a study of pianists, Montes et al. (1993) noted that variation in EMG activity was related to stroke intensity.

Figure 3. Surface EMG pattern for the index finger of the right hand, rest stroke, measure 5, second part.

Figure 4. Surface EMG pattern for the index finger of the right hand, free stroke, measure 5, second part.

In Figure 4, while crossing strings using the free stroke technique, the explanation for the surge in muscular voltage levels at the beginning of the action when approaching the string, and the reduction of these in the final moments of the action, may lie in the fact that when the free stroke is executed the guitarist does not have a point of support or reference to complete the action, and must apply greater control over the movement and speed of execution prior to plucking the string. To do otherwise an uncontrolled movement may occur in the impulse of the final action, and, as a consequence, an unintended musical effect may result.

This data corroborates the findings of Carlevaro (1979) on the mechanics of attack, which indicates that work is not completed with the attack itself, but must be complemented by counterforce as strong as or stronger than the original action to avoid abandoning the finger once plucking is completed. This is due to the fact that, in this musical situation, results

indicate that the force applied is greater in the phase of impulse towards the string and, at the time of completion of the impulse, this may require compensatory action of the extensor muscles of the fingers to balance the action. This counteraction demonstrates the system may dictate different activation thresholds for each of the muscle groups in order to achieve greater control over the action (Feldman, 1998).

In Figure 5, during the execution of the technically challenging section using the rest stroke technique, the second string was plucked with the index finger, then the first string was plucked with the middle finger. At the moment of plucking, the lowest muscle voltage value was recorded in both repetitions.

Figure 5. Surface EMG pattern for the middle finger of the right hand, rest stroke, measure 3, second part.

The explanation for why voltage levels increase at the beginning of the action of the middle finger may be that at this moment an impulse must be generated to ensure that the finger reaches the corresponding string and presses it with the required force while counteracting the action of the finger extensors in the opposite direction.

As illustrated in Figure 6, when the free stroke was, the level of activation (voltage) dropped at the moment of plucking and increased at the end of the action, i.e., when the middle finger had finished plucking.

The reason why the maximum level activation (voltage) is reached when the string has been plucked (graph value 17), is due to adjustments that may be related to a choice of musical interpretation - something the interpreter decided to apply when performing an ascending scale.

Lastly, the temporal stability presented by Participant 1 in all of the musical passages analysed using both fingers and techniques should be noted.

This provides a clear example of the degree of precision and control that expert performers employ when interpreting a piece.

Figure 6. Surface EMG pattern for the middle finger of the right hand, free stroke, measure 3, second part.

Participant 2

Figure 7. Surface EMG pattern for the index finger of the right hand, rest stroke, measure 6, first part.

In Figure 7, during the execution of the technical section using the rest stroke technique, the participant (guitarist 2) changes from the first string plucked with the middle finger to the second which is plucked with the index finger.

This activation pattern, which lasts from the start of the action until the time of the stroke, can be explained by the need to adjust finger action to control intensity in the execution of these notes.

In Figure 8, when the guitarist plays the passage using the rest stroke technique, the decrease in muscle voltage as the finger approaches the strings to be plucked and during plucking may be motivated by the desire to ensure greater motor control over the execution of the plucking, and to properly adjust this to the intensity with which the corresponding note is to be executed.

As shown in Figure 9, when the guitarist changed from plucking the second string with the index finger to plucking the third string with the middle finger, an increase in the level of muscular voltage was registered during the stroke. This may be due to an attempt to produce a specifically desired tone.

Figure 8. Surface EMG pattern for the index finger of the right hand, free stroke, measure 6, first part.

Figure 9. Surface EMG pattern for the middle finger of the right hand, rest stroke, measure 6, second part.

Also, when changing the fingering of the right hand required for the interpretation of the score (index and middle fingers), a situation arises in which the fingering is reversed (with the index finger on the second string and the middle finger on the first string). It is important to note that when playing guitar scales, the index and middle fingers are used primarily, but the ring finger and/or thumb are also used to avoid awkward string crossings Wen-Tzu (1999). The graph shows that this issue does not affect the EMG voltage pattern. The levels remain constant in the two repetitions in the most important moments, which correspond to contact with the string, plucking, and the end of the action (graph values 9-17).

Figure 10. Surface EMG pattern for the middle finger of the right hand, free stroke, measure 6, second part.

In Figure 10 (as in Figure 9 with the rest stroke technique), when the guitarist performed the musical passage using the rest stroke technique, the highest values were recorded at the moment of the stroke. This is comparable to other situations using the index finger in both techniques mentioned above. This may be due to anatomical-functional limitations which intervene in the action of the middle finger, i.e., the middle finger is not completely independent like the index finger because when it is free next to the index finger the intertendinous connection joins it with the ring finger (Latarjet and Ruiz Liard, 1990). These higher values may also be the result of adjustments made by the performer meant to facilitate the action of the finger. In this situation, the same reverse fingering mentioned above takes place. This added challenge did not affect the surface EMG pattern.

Lastly, Interpreter 2 presented similar temporal parameters in all of the repetitions and situations analysed, demonstrating a clear mastery of musical execution.

CONCLUSION

The results of this study indicated a high degree of stability and consistency in terms of muscle requirements for both participants, which is evidence of the excellent motor control

required to become an expert guitarist. It is important to note that each of the performers presents different surface EMG patterns in the fingers (index and middle) and for the stroke systems studied (rest stroke and free stroke), but inter-subject trials were similar for all of the musical passages.

The data showed that Participant 1 presented the same index finger pattern at the moment of the stroke and afterwards in both techniques. It also showed an identical pattern for the middle finger when approaching the strings, during the attack, and in the final stages of the actions.

Participant 2 presented a single pattern for the index finger and a different pattern for the middle finger on the approach to the strings, during the stroke, and at the end of the action.

Of particular importance is the fact that sometimes the participants presented variable muscle activation values in the initial and end phases of their actions for each of the repetitions studied in all musical situations, but there was clear pattern of similar values – which at times were even identical – in key moments of technical difficulty such as contacting and plucking the strings. This means that muscle activation during plucking is directly related to the intensity of execution that the guitarists chose to employ for the interpretation of each note.

Lastly, it should be noted that both performers maintained a high degree of temporal stability in the different musical passages, which demonstrates the extremely high degree of accuracy applied to the interpretation of the musical piece.

In summary, the current study provides an empirical basis to help understand underlying motor control processes in classical guitar performance technique. Further it establishes a process for exploring instrumental performance technique that may be understood as arising from performers' individualized musical motivations or approaches to performing on the guitar.

INTRODUCTION

In this chapter we will describe briefly the pathophysiological mechanisms of central nystagmus generation, proceed with the description of bedside examination of the patient with sudden onset of vertigo and unsteadiness. We will present the results of 9 patients with stroke diagnosis who were during the year 2013 admitted to our Neurological Emergency Department and who came with sudden onset of vertigo and unsteadiness as the leading symptom of illness. On the basis of this results we will discuss the importance of recognition of the impairment of central vestibular pathways as solely symptoms or additional symptoms in the early diagnosis of cerebral stroke. The therapeutic guidelines will be presented as well.

Pathophysiological Mechanisms of Central Nystagmus Generation.

Vestibular pathways run from vestibular nerve and vestibular nuclei mostly through the fibers of medial longitudinal fasciculus (MLF) to the oculomotor nucleus and supranuclear integration centers in the midbrain (interstitial nucleus of Cajal (iC) and rostral interstitial medial longitudinal fasciculus (riMLF) nucleus).

Sometimes pathophysiology of the anatomical structures can explain the visible nystagmus but occasionally the topography of the nystagmus generation is not so simple.

Nevertheless, we will try to present the pathophysiological mechanisms which lead to the generation of central vestibular nystagmus.

Gaze Holding

To start an eye movement, a burst of activity from motoneurons is needed. To maintain the gaze in one position, activity from neurons which differ cytoarchitecturally from motoneurons is necessary. Those neurons provide a constant tonic input to the ocular muscles and they are involved in gaze-holding. They form the so called neural integrator and additional clusters of cells which are interspread between and around the fasciculus of MLF [1]. The neural integrator for horizontal eye movements is located in the vestibular nucleus/nucleus prepositus hypoglossi complex [2,3]. Cell clusters around the crossing of the MLF fibers in lower pons (paramedial pontine reticular formation (PPRF)) are demonstrated to be involved in gaze holding as well [4]. In addition, the flocculus of the cerebellum supports gaze holding. For vertical gaze holding the (iC) in the mesencephalon is proved to be responsible [5].

If maintenance of stable conjugate eye deviation away from the primary position is not possible, the eyes drift back to the center and a corrective saccade (or fast phase) brings the eye back to the desired position. This happens for as long as the attempt of holding the eyes fixed on one object in the lateral position is present. The result is gaze-evoked nystagmus. The gaze evoked nystagmus changes it's direction with the change of gaze position. It is always present in the direction of gaze (Figure 1). The gaze evoked nystagmus generally appears on attempted gaze, but it can also occur spontaneously because of the difference between the null and the midposition of the eye. Internuclear ophthalmoplegia (INO) is a pathological oculomotor sign attributed to unilateral or bilateral MLF lesions. It is characterized by slowing of adduction of the eye on the side of the lesion and a gaze evoked nystagmus of the contralateral eye. INO can be present bilaterally [6]. The slowing of adduction is better visible in cases of larger compared to smaller lesions.

Figure 1. Gaze evoked nystagmus to the right, to the left, upwards and downwards. Arrows show the direction of eye movements and the amplitude of the movement of each eye.

Yaw, Roll and Pitch Plane

According to Brandt and Dieterich [7] signs and symptoms of vestibular dysfunction can be divided according to three planes of action of the vestibuloocular reflex (VOR): yaw, roll and pitch plane.

Figure 2. Horizontal nystagmus to the left, the arrows show that both eyes are moving with the same amplitude and in the same direction.

Spontaneous horizontal nystagmus is a VOR dysfunction in yaw plane (Figure 2). In most cases it is caused by the lesion of vestibular sense organ or nerve. It is rarely caused by central lesions but it can be present if the lesion involves a small part of the medial and superior vestibular nuclei and the adjacent centers for gaze holding (PPRF). Postural signs in the same plane are lateral head tilt and lateral body tilt toward the side of the lesion.

Roll Plane

If a unilateral central lesion of the vestibular afferent pathways happens, it mostly affects the so called graviceptive pathways which transduce the information from vertical semicircular canals and otoliths. The result is an imbalance of the vestibular input (tone imbalance) in the roll plane with a torsional nystagmus (Figure 3).

Lesions of iC cause an ipsiversional torsional nystagmus while lesion of riMLF nucleus is responsible for a contralateral torsional nystagmus [8]. Postural signs are head and body tilt to the side opposite to the lesion, sometimes skew deviation with the undermost eye on the side opposite to the lesion and ocular torsion (Figure 4). Skew deviation can also accompany peripheral vestibular lesion of utricle [9]. Ocular torsion is present, but it can not be seen by bedside examination. It can be demonstrated by fundus photography. Therefore we will not discuss this symptom further. The triad of symptoms head tilt, skew deviation and ocular torsion is called ocular tilt reaction (OTR). It can be present some peripheral as well as central lesions of the vestibular pathways up to the mesencephalon.

Figure 3. Torsional nystagmus. The arrows show the direction of eye movements.

Figure 4. A schematic drawing of the vestibular syndromes in roll plane. On the labyrinthine and pontine level, head tilt and skew deviation are toward the lesion side, on the mezencephalic level they are toward the contralateral side (according to Brandt and Dieterich 1995).

Pitch Plane

Bilateral lesions of the central vestibular pathways result in vertical upbit nystagmus (pitch plane) and forward or backward body tilt.

Flocculus

Flocculus of the cerebellum supports the gaze holding, unilateral lesions of flocculus and its connections to the vestibular nuclei result in gaze holding deficit (Buettner and Grundei 1994) and failure of fixation suppression of the vestibular nystagmus [10]. Bilateral lesions of flocculus result in downbeat nystagmus.

BEDSIDE EXAMINATION

Only neurootological tests which can enlarge the examination done by neurologist, and only the tests which can be done on bedside will be discussed. Various very useful neurootological tests for which some instruments are needed, will be skipped. The performance of tests already described in details previously in this book will not be repeated.

The spontaneous nystagmus caused by a damage or irritation of the vestibular apparatus/nerve was already previously described. If the eye movements are horizontal, our attendance must be directed to both eyes because if both eyes are moving with the same amplitude and in the same direction, we can call it horizontal “vestibular” nystagmus (figure No 2). If both eyes a moving spontaneously with torsion of both eyes in one direction, it is the spontaneous torsional nystagmus (figure No 3). If the eyes are moving spontaneously up or spontaneously down, this is the spontaneous vertical nystagmus.

If the eyes are not moving spontaneously at the moment of examination, we provoke the nystagmus by positional tests. The horizontal vestibular nystagmus can be provoked also if the patient fixate on a target 30° to the right and then to the left. The nystagmus will occur only in one direction and both eyes will still be moving with the same amplitude (according to Alexander’s I degree).

The next test used to provoke a horizontal “vestibular” nystagmus is the head shaking test. Nystagmus duration depends on the magnitude of the vestibular damage.

Next we try to provoke the gaze evoked nystagmus. The patient fixate on a target 30° to the left, to the right, up and down. The nystagmus which appears on gaze fixation is called the gaze evoked nystagmus. Usually with horizontal gaze fixation the amplitude of the abducted eye is larger then the amplitude of the adducted eye (figure No 2). The nystagmus changes it’s direction with the direction of gaze. If the patient moves his abducted eye about 40° laterally the so called end point nystagmus can occur which is not a sign of illness. This nystagmus usually stops after a few second. Asking the patient to fixate his gaze at this position, we can sometimes discover a gaze evoked nystagmus which is a remnant of a previous illness of the peripheral or central vestibular pathways.

The gaze evoked nystagmus can be caused by the damage of flocculo-vestibular connections. It changes the direction with the direction of gaze. According to our personal observations, in this case the evoked nystagmus is with equal amplitudes on both eyes,

usually with low frequency. For this observation we don't have any experimental confirmation.

Vertical fixational nystagmus appears at upward or downward gaze fixation. More often is the upward nystagmus.

Skew Deviation

By horizontal head impuls (or head thrust) test a recent horizontal canal paresis can be demonstrated. The observer can be uncertain about the result in the case of mild or moderate lateral canal paresis.

Caloric test is the other way to test if canal paresis exists. The standard bithermal caloric test with hot (44°) and cold (30°) water can not be easily performed at bedside. Therefore we use the test described by Torok. The test is done first with a weak stimulus (10 ml) and then with a strong stimulus (100 ml) of 20° cold water. The postcaloric nystagmus duration is measured in seconds. The postcaloric nystagmus lasts for about 50 seconds after weak stimulus application, and about 90 seconds after the strong stimulus application. If a more than 25% asymmetry between the left and the right side exists, the patient suffers of a horizontal canal paresis [11]. The general recommendation for the time of caloric test accomplishment is more than 4 days after beginning of sudden vertigo.

The Vestibulospinal Tests

The past pointing test is positive in terms of deviation of the arm to one side during the attempt to touch the examiners finger with closed eyes. It is a nice demonstration of hypotonia of arm muscles after sudden impairment of the vestibular apparatus.

Romberg test and "sharpened" Romberg test although not specific for vestibular instability, can be used at the beginning of the illness when a clear inclination or swaying to one side can be demonstrated. During the "sharpened" Romberg test the patient stand in the tandem heel-to-toe position with eyes closed and arms folded against the chest. He inclines or falls toward the impaired side.

Tandem walking (heel- to- toe) is not possible in acute vestibular illness.

METHODS

We performed a retrospective study of 723 in-patients of our Neurological Emergency Department admitted to the Department during the year 2013. There were 53% of women, 47% of men, between 18 and 78 years (mean 42 years). The patients with sudden vertigo and sudden instability as the dominant symptom of illness were selected. Patients with vertigo and hearing loss were excluded from this study. All patients where first seen by a neurologist. A computerized tomography (CT) scan was performed before the admission and repeated within 22 to 36 hours, or earlier, in cases of clinical deterioration. In some patients a diffusion weighted magnetic resonance imaging was performed (MR) as additional neuroimaging tool.

Each patient with vertigo was also seen by a ENT specialist-neurotologist, on the first or on the second day of admission.

In all patients with suspected stroke, the evaluation of blood vessels of head and neck was done by using Carotid Doppler Sonography (CDS), Transcranial Doppler (TCD) and CT angiography.

Therapeutic process for patients with suspected stroke included their treatment in the stroke unit following the protocol which was made based on recommendation of current guidelines [12, 13].

RESULTS

Out of 723 in-patients, only 22 were hospitalized because of sudden vertigo and sudden instability as the dominant symptom of illness. After precise clinical examination, 9 patients were diagnosed as cerebral stroke, 13 as vestibular neuronitis.

The results of the patients with stroke are shown on Table 1.

N.J.	26	MR	Mezencephalic inf L	No	Spont torsional to the R Haed tilt R HIT: uncertain cal test: symmet vest. spin tests: incl to the R
K.S.	55	CT	Cerbl inf R Sten vert a R	Yes	Gaze evok ny to R HIT: symmet vest. spin tests: ataxia

Cerbl - cerebellar, inf - infarction, R - right, sten - stenosis, vert -vertebral, a - artery, L - left, ocl - occlusion, mezenceph - mezencephalic, Thalam - Thalamic, Sy - syndroma, Midbr - Midbrain, spont - spontaneous, H - horizontal, ny - nystagmus, HIT - head impuls test, cal - caloric, FFS - failure of fixation suppression, vest spin – vestibulospinal, gaze evok – gaze evoked, symmet – symmetrical, incl – inclination, dev – deviation.

The patients were between 26 and 75 years old, 5 female, 4 male. CT scan was done in all of them at the moment of admission, and was repeated in following 22-36 hours from the symptom onset. MR was done in 5 patients.

Isolated cerebellar infarction was present in 4 patients, pontine and cerebellar infarction in 1 patient. Isolated pontine infarction in 1, mezencephalic infarction in two patients, thalamic infarction together with brainstem syndrome in one.

Unilateral stenosis or occlusion of vertebral artery was demonstrated in four patients (3 with cerebellar infarction, 1 with pontine infarction). Neurotological finding is listed in details. Except neurotological positive finding, additional neurological signs (involvement of long pathways, other cranial nerve (except vestib. nerve and abducens nerve) lesions, hemihypesthesia, dismetria) were present in 7 patients, in two they were not.

Spontaneous horizontal nystagmus was present in one patient, peripheral vestibular etiology was demonstrated by head impulse test (HIT) and caloric testing, as well as by vestibulospinal tests (toward one side). The cerebellar involvement was demonstrated with unilateral failure of fixation suppression (FFS).

Spontaneous torsional nystagmus was present in two patients. One had torsional nystagmus to the left side, skew deviation with the lower right eye, inclination to the right while performing the vestibulospinal tests, symmetrical HIT and symmetrical caloric test. The other had spontaneous torsional nystagmus to the right, head tilt to the left and inclination to the left while performing the vestibulospinal tests. HIT was symmetrical as well as the caloric test.

Three patients with cerebellar infarction had gaze evoked nystagmus: one bilateral while two to the side of cerebellar lesion. HIT and the caloric test were symmetrical in all three patients. One had bilateral FFS, the other two unilateral, on the side of cerebellar lesion. Ataxia was present in all patients while performing the vestibulospinal tests.

The patient with pontine and cerebellar lesion had abducens nerve paresis on the left side and gaze evoked nystagmus to the right. HIT was uncertain, caloric test symmetrical, and he did not incline to one side while performing the vestibulospinal tests.

One patient had isolated pontine lesion on the right side. Internuclear ophthalmoplegia (INO) was present at the side of lesion. HIT was judged as uncertain. Caloric test and vestibulospinal tests were not performed because patient's general condition worsened.

In one patient a thalamic infarction was visible with MR, but clinical examination demonstrated that a brainstem syndrome is present in addition. An abducens nerve paresis was present on the left side, a gaze evoked nystagmus on the right side. HIT was symmetrical, caloric test symmetrical, during the vestibulospinal tests he inclined to the left.

Therapy

Only 1 of 9 patients arrived at the hospital within the therapeutic window of 4.5 hours for administration of intravenous thrombolytic therapy and was consequently treated with it. The secondary stroke prevention was done by using Aspirin, dose 300 mg, which was introduced in the first 48 hours from symptoms onset. Patients were also treated with intravenous solution (0.9% Sodium Chloride and Ringer) as well as antiemetic, and other therapy for control of cerebrovascular risk factors.

DISCUSSION

To recognize the impairment of central vestibular pathways in patient with sudden onset of vertigo and unsteadiness is of crucial importance in neurological practice, especially in Neurological Emergency Units.

During last few years the importance of this recognition was stressed in several publications (14, 15, 16, 17).

Among 723 patients hospitalized at Emergency Neurology Department of Clinical Centre of Serbia, 22 came with sudden vertigo and unsteadiness as a leading symptom of their illness.

Thirteen of them were diagnosed as vestibular neuritis and treated accordingly. Nine of them were diagnosed as cerebral stroke. We analyzed which neurotological signs accompanied which localization of stroke and how effective single diagnostic procedures were in establishing the diagnosis.

In cerebellar stroke patients, only one patient had a peripheral vestibular impairment additionally. This impairment was recognized by typical signs of peripheral vestibular damage: horizontal nystagmus, positive HIT, body inclination toward the lesion side, unilateral paresis in caloric test. The cerebellar sign was in this case the unilateral FFS. Besides neurotological, the patient had neurological signs as explained on the table. The neurotological signs demonstrated at the bedside, that a peripheral vestibular damage is present, signs of cerebellar involvement were revealed after a few days when the caloric test was performed. In this case, crucial for the stroke diagnosis was the neurological examination.

Three other patients with cerebellar stroke had the unilateral or bilateral gaze-evoked nystagmus. Two of them had unilateral or bilateral FFS. In two patients with cerebellar stroke additional neurological signs were present. In one patient neurological signs were not present, the only neurotological sign of central impairment was gaze evoked nystagmus. On the basis of this sign, the CT imaging was performed and stroke was revealed. Therefore, we underline that gaze evoked nystagmus is an important sign of the damage of central vestibular pathways (in this case probably cerebello-vestibular connections).

The first patient with mesencephalic infarction, had typical symptoms: spontaneous torsional ny to the left, skew deviation with the lower R eye, simetrical caloric test, body inclination to the R. Additional neurological sign were present.

The second patient with mesencephalic infarction, a young woman of 28 years, only a spontaneous torsional nystagmus to the right was present together with the head tilt to the right. None of additional neurological signs were present. In this patient, the suspicion of brain stroke was raised only on the basis of neurotological signs, and with MR imaging, the suspicion was confirmed.

In patients with pontine infarction the central vestibular signs were typical: INO and abducens paresis with gaze evoked nystagmus to the opposite side.

The greatest importance of central vestibular pathways impairment recognition is in patients who don't have additional neurological signs. This was the case in our two patients (one with cerebellar and one with mesencephalic stroke). Grace to this recognition, the proper therapy was immediately administered and all possible risk factor were explored in order of second stroke prevention.

Kattah and coworkers (17) introduced the acronym of HINTS for head impuls, nystagmus and test of skew, as the most important steps of bedside oculomotor examination (in differentiation between the peripheral vestibular impairment and stroke). The group of Kattah and coworkers observed the skew deviation by means of prism cross cover test. In our patients skew deviation judgement was not done by prism cross cover test, therefore we can not comment their finding of skew deviation. However with a small number of patients with brainstem lesion, we would not expect a greater percentage of skew. We confirm the importance of the given acronym. In our patients, besides the gaze evoked nystagmus, an important diagnostic sign was FFS which discovered cerebellar dysfunction.

Chapter 69

EATING HABITS, FALLS AND STROKE RISK

Bajram Kamberi^{1,*} and Gojart Kamberi²

¹Clinical Hospital Tetovo, Tetovo, Republic of Macedonia

²State University of Tetovo, Tetovo, Republic of Macedonia

INTRODUCTION

Ischemic stroke (IS) the most common type of stroke accounts for 70% to 88% of all stroke events (Ayala et al., 2002: 1197-1201; European Stroke Organization, 2008: 457-507; Brott et al., 2011: e464-e540; Chen et al., 2013: 91-95). As the commonest neurological disease, ranking only behind heart disease and cancer represents the third largest cause of death and leading cause of long-term disability (Allen and Bayraktutan, 2008: 105-116; Planjar-Prvan, 2010: 3-8; Furie et al., 2011: 227-276). Before menopause women more rarely suffer from stroke, but difference among the elderly become blurred (Thom et al., 2006: e8-e151). IS most often occurs in the seventh and eighth decades of life, whereby about ten percent of IS occurs at age of 45 (Nedelchev et al., 2005: 191-195).

According to the American Heart Association, 795.000 people experience a new or recurrent stroke each year in the United States (Go et al., 2013: e6-e245). It is common for the patients who experience an IS to have both modifiable and non-modifiable risk factors for stroke (Khan et al., 2009: 62-7) because evolution of atherosclerosis and IS as clinical events are related to several modifiable and non-modifiable risk factors and that lowering levels of these factors result in benefit. Also, the blood lipid categories include a comprehensive list of lipids known as factor that can accelerate evolution of atherosclerosis (Ding, 2008: 27-31) or are protective and, lower the cardiovascular disease risk (Cuevas et al., 2000: 143-8; Brown and Hu, 2001: 673-86). Atherosclerosis is most frequent reason for the non-cardio embolic ischemic stroke (80%), while 20% from ischemic stroke are cardio embolic, and most frequent reason for their appearance is atrial fibrillation (European Stroke Organization, 2008: 457-507; Brott et al., 2011: e464-e540). In the general population and patients cohorts, risk factor profiles changed with increasing age (Andersen et al., 2010: 2768-2774; Berry et al., 2012: 321-329). A review from 2012 (Gayle et al., 2012: 244-250) reveals that nutrition can

* Corresponding Author's Email: bajram_kamberi@yahoo.com.

impact factors that increase the risk of stroke. Similarly to that, in a guideline (Furie et al., 2011: 227-276) and a case-control study (O'Donnell et al., 2010: 112-123) a healthy diet, could substantially reduce the burden of stroke (European Stroke Organization, 2008: 457-507) particularly making simple lifestyle modification (Allen, and Bayraktutan, 2008: 105-116) and/or with effective risk factor management (Gordon et al., 2004: 1230-1240; Furie et al., 2011: 227-276; Gayle et al., 2012: 244-250). Therapeutic lifestyle modifications to reduce high blood lipids and thus decreased stroke risk are based on decreased consumption of saturated fat and cholesterol (Gordon et al., 2004: 1230-1240) including moderate consumption of red meat, sausages and processed products (Lichtenstein et al., 2006: 82-96).

It is recognized that changing dietary habits of ethnic groups in Europe (Penelope and Santosh, 2008: 203-15) from a public health perspective are the basic intervention measures in concept of an integrate approach for prevention of main non communicable diseases such as cardiovascular disease, including stroke (European Public Health Monitoring, 2011). In Finland the diet (particularly fat consumption) has changed and these changes have led to a major reduction in population serum cholesterol, blood pressure levels and ischemic heart disease mortality (Puska et al., 2012: 245-251).

The Former Yugoslav Republic of Macedonia (henceforth Macedonia, or the Republic of Macedonia proclaimed its independence in 1991 when the transition period officially started was one of the poorest republic in former Yugoslavia and now is one of the poorest countries in Europe (Shukarov, 2011). In the current situation the Republic of Macedonia (RM) is a particularly significant example of the redefinition of the state's economic role with disastrous socioeconomic results. As a result, present contrast between the local structures and a nation state-centric viewpoint of society, the effect of diverse socioeconomic policies, administrations, and/or organizations as elements of a system give rise to reflect the dynamic nature of the consequences of less power to regulate socioeconomic processes (Gjorgjev et al., 2006: Shukarov, 2011; Trenchov, 2012: 1-12). In general the transition period in Macedonia was considered to cause changes in lifestyle and health risk behaviors among Macedonian people (Macedonian Health Ministry, 2014: 1-30). An unhealthy diet as consequence of a transition in lifestyles that leads to increased risk of non communicable disease was noticeable (Macedonian Health Ministry, 2004: 9-10). Actually, dietary habits and physical activity levels monitoring as basis for new health promotion strategy to reduce non communicable disease mortality in Macedonia were prominent themes throughout the several investigations (Kosevska, 2004; Simovska-Jarevska et al., 2012: 370-374; Simovska-Jarevska et al., 2013: 20-30). In the background of the health determinants (Macedonian Health Ministry, 2014a), the results obtained from the national "cross-sectional" studies in the Republic of Macedonia with the aim to analyze and evaluate data for monitoring of eating habits in 2011 (Simovska-Jarevska et al., 2012: 370-374) and data on eating habits related to socioeconomic status of the participants in 2012 (Simovska-Jarevska et al., 2013: 20-30), indicate changes in eating habits (Simovska-Jarevska, 2012: 370-374) and socioeconomic difference (Simovska-Jarevska et al., 2013: 20-30) in educational levels and income of the consumption of the main health related foods of population aged 10 to 64 years. Regarding consumption of meat and meat products, most of the study participants consumed chicken and pork, less fish, little lamb and veal; too participants with higher education and higher income, more frequently used fish and beef meat (Simovska-Jarevska, 2013: 20-30). In literature, a differences in eating habits as matter of faith also was observed; Christian believers have experience stroke more frequently than Muslim believers as results of pork meat consumption

(Kosevska, 2004; Ejub et al., 2004: 33) and/or the type of fats in meats (Petrovic-Oggiano et al., 2011: 5-11).

On the basis of these findings of this literature review, the aim of this prospectively case-controlled study was to compare the possible adverse health effects of two different diets due to religious beliefs (consumption or not of pork meat, converted simply “users” versus “non-users”) on stroke risk and to determine whether the changes in blood lipids levels in patients who had an acute phase of first-ever ischemic stroke disease (FIS) and normal control subjects were different between users and non users in both study groups.

MATERIAL AND METHODS

Participants

The study was conducted in Tetovo region in RM, including eligible 425 participants aged from 18 to 87 years of age, with a clinical assessment, a physical examination and with determination of lipid profile from a fasting blood sample measured at entry and dietary history was noted. The protocol was approved by the authority at Clinical Hospital Tetovo. All participants gave written informed consent. The participants who withdrew before completion of the study or who did not have all the required data to derive a response status were classified as no responders and didn't take part in the present study. The clinical study conducted according to good clinical practices. All eligible participants were randomization was performed centrally according to a computer-generated scheme and was stratified by age, gender, religion, eating habits and blood samples collected on admission. In an exploratory analysis, accessibility participants based on the initial examinations (the clinical features and neuroradiological findings) were grouped into two study groups: patients with acute FIS (EG) and normal control subjects (CG), but analysis was done by dietary habits stratification. Disparities in eating habits as matter of faith was defined as the differences in pork meat consumption based on religion dietary restrictions. For objective assessment of the probability of first stroke episode for two types of diet due to religious beliefs assessment of dietary habits was conducted using self-designed questionnaire for the purpose of our previous study (Kamberi and Kamberi, 2012: 181-8) and a physical and neurological examination. Considering the popularity of lifestyle risk factors for IS to simplify the expressed results of our study, according the assessment of the frequency of consumption of various meats: beef/pork, regular consumer of pork meat were the first “users” subgroup included respondents who were once every day, once a week, once a month or once upon a time, whereas regular consumer of beef meat were the second “non-users” subgroup included respondents who never before consume pork meat. Detailed description of the design and methods and of its recruitment procedures and main results has been published (Kamberi et al., 2011: 68-75; Kamberi and Kamberi, 2012: 181-8).

In brief, the present study included a total of 231 patients (126 men and 105 women with an average of 65.7 years) with clinically and imagining verified diagnosis of acute first-ever ischemic stroke disease (FIS) at the Department of Neurology within Clinical Hospital in Tetovo, a secondary care teaching hospital, who were hospitalized between September 1, 2008 and August 31, 2010. The control group consisted of 194 randomly selected healthy subjects with similar gender representation without clinical and anamnesis data for stroke and

related clinical entities. Patients were verified with acute FIS using a detailed taken anamnesis, clinical detailed neurological examination and by means of computed tomography (CT) and/or nuclear magnetic resonance imaging (MRI) of the brain.

Data Analysis

Demographic and baseline characteristics of participants were summarized by descriptive analyses stratified by age, sex, religion and cohort of the frequency distribution of beef and/or pork meat in relation to FIS onset. Also, lipid profile was a priority measure in this study.

The fasting lipid profile was evaluated within days after the stroke onset or at entry and consisted of plasma concentration of total cholesterol (total-chol) (< 5.2 mmol/L, > 5.2 mmol/L,) triglycerides (Trig) (< 1.70 mmol/L, > 1.70 mmol/L, low density cholesterol (LDL-chol) (< 4.1 mmol/L, > 4.1 mmol/L) and high density cholesterol (HDL-chol) < 0.9 mmol/L.

The type of eating habits of participants due to religious beliefs dichotomized as consumption or not of pork meat, typified as simple “users” versus “non-users” and the consumption of pork meat was analyzed by randomization strata into “Yes” and “No”.

The age, gender and religion of participants were the statistical independent variables. The age of participants were coded into five groups less than or equal to 49, between 50 and 59, from 60 and 69, between 70 and 79 and equal or greater than 80. The participant's doctrine were divided into the categories Muslim believer and Christian believer.

Data analysis was carried out using SPSS statistical software, version 17.0. Numerical data was expressed as mean $\pm$ SD. Patients and control subjects variables were compared by t-test for independent samples and unpaired test for univariate analysis. Confidence intervals were computed for all variables. Statistical differences were determined mainly through comparison of confidence intervals to assess consistency of associations and correlations were considered statistically significant if the p value was < 0.05 . All statistical tests were two-tailed.

Study Limitation

In this selected cohort, data were weighted to reflect the selected characteristic of population in Tetovo region. According to the official census figures of 2002, Macedonia's population consist of a majority of ethnic Macedonians (64.18%, predominately Orthodox, with a small Muslim minority), followed by ethnic Albanians (25.17%, predominately Muslims, with a smattering of Catholics and Orthodox), plus other ethnic minorities (Macedonian State Statistical Office, 2005). There most of Macedonian's ethnic Albanians were and are concentrated in the western part of the country, and in certain municipalities (principally around Tetovo and Gostivar, an administrative area of Pollog). There Albanians represent the majority population (Trenchov, 2012: 1-12).

RESULTS

During the two years period, data were collected from eligible 425 residents from Tetovo region as study participants. The gender of the patients was presented in 126 (54, 55%) men and 105 (45, 45%) of patients were female. We found statistically non significant differences (Pearson Chi-Square = 0.523, $p = 0.470$) between patients and control subjects in the

performance of the gender (Table 1). The age at which FIS occurred was no significantly higher in men (66.17 ± 9.48 years) compared to women (65.14 ± 10.097 years). The mean age of the patients was 65.70 ± 9.76 years. Normal control subjects were in the group whose average was the youngest, 52.09 ± 14.49 years. These differences in the average age among participants normal control subjects and patients was confirmed statistically ($t = 11.35$, $p = 0.000$), so we can conclude that the age of patients with FIS has significant impact on onset of disease.

The study participants were dichotomized into “users” and “non users” and observed after dividing they into age subgroups presented in Table 2. The youngest patient was 37, and the oldest was 87 years old. The mean (median) value indicates that 45 (19.48%) of patients were in the age group of 50-59 years, 172 (74.46%) of patients were older than 60 years, while only 14 (6.06%) of patients were in the age group of 18-49 years.

As depicted in the table 2, regarding consumption of meat beef and/or pork at the 425 participant, most of the study participants consume beef and never before pork 312 (73.41%). Study results showed that 113 (26.59%) of participants from all age groups regularly consume pork meat, most of them 39/113 (34.51%) were from 50 to 59 years. With aging, the frequency of users decreased, 19/113 (16.81%) were from 60 to 69 years and 27/113 (23.09%) were from 70 to 79 years, while 7/113 (6.19%) were over 80 years.

Compared with the results obtained in all age groups, a great part of patients with FIS were users in the age group of 50 to 59 years 14/231 (6.06%), from 60 to 69 years were 12/231 (5.19%), and 21/231 (9.09%) were from 70 to 79 years, while 5/231 (2.16%) were over 80 years.

Table 1. Distribution of the study groups by gender

	Control	Patients	
Gender	subjects	with FIS	Total
	(n, %)	(n, %)	(n, %)
Male	99 (51.03)	126 (54.55)	225 (52.94)
Female	95 (48.97)	105 (45.45)	200 (47.06)
Total	194 (100)	231 (100)	425 (100)

Table 2. Dividing the study groups into age subgroups

Age	Control subjects		Patients with FIS	
Groups	Total	Users	Total	Users
(years)	(n, %)	(n, %)	(n, %)	(n, %)
18-49	79 (40.72)	17 (8.76)	14 (6.06)	4 (1.73)
50-59	65 (33.51)	25 (12.89)	45 (19.48)	14 (6.06)
60-69	26 (13.40)	7 (3.61)	83 (35.93)	12 (5.19)
70-79	20 (10.31)	6 (3.09)	72 (31.17)	21 (9.09)
80 >	4 (2.06)	2 (1.03)	17 (7.36)	5 (2.16)

Table 3. Sample characteristics relating to pork consumers

Variables	FIS` s disease		Total
	Yes	No	
Users (n, %)	56 (24.24)	57 (29.38)	113 (26.59)
Non-users (n, %)	175 (75.76)	137(70.62)	312 (73.41)
Total (n, %)	231 (100)	194 (100)	425 (100)

Table 4. Estimates of the relative risk between two study cohorts

Type of study	Value	95% Confidence limits	
Case-Control (Odds Ratio)	0.769	0.500	1.184
Cohort FIS	0.884	0.716	1.09
Cohort CG	0.8677	0.923	1.439

There were 79 normal control subjects whose age was less than 49 among them, 17 (8.76%) were users. The age of 65 normal control subjects was between 50 to 59 years of which 25 (12.89%) were users. There were 26 normal control subjects with age 60-69 of which 7 (3.61%) were users. The age of 20 normal control subjects was between 70 to 79 years of which 6 (3.09%) were users. There were 4 normal control subjects with age greater than or equal to 80 among them 2 (1.03%) were users.

To compare the probability of first stroke episode for two types of diet due to religious beliefs (consumption or not of pork meat, dichotomized into “Yes” and “No”) between patients with FIS and normal control subjects according to food frequency data, all analyzed participants were categorized into users and non-users, while an about equal number of users. The contingency Table 3 displays the frequencies for each exposure.

In both groups dominate frequency of non-users. For these differences in the disease onset were presented in Table 3 we calculated odds ratios for the association of ischemic stroke with selected dietary habits; employing Chi-square test (table 4).

The odds ratio, show in table 4, provide an estimates of the relative risk. This estimate indicates that the odds ratio of FIS disease was 0.77 times higher in the users group; but the odds ratio was low with tightly confidence limits (95% CI = 0.500-1.184).

The participants with Christian believer were 122 and among them, 113 (92.62%) were users, while 9 (7.38%) were non users. The participants with Muslim believer were 303 and among them, not have users. Association between the consumption of pork meat and faith of patients with FIS is shown in Figure 1. The odds ratio from example analysis of crosstabs by chi-square statistics has a value (OR = 0.23, 95% CI = 0.009-0.061) suggesting the relative risk. FIS` disease was with more number of users in Christianity cohort, but according to the low value of OR with tightly confidence limits we can conclude that the association between these two parameters was weak and statistically insignificant ($p > 0.05$).

Additional analysis was performed to compare the lipid profile between patients and control subjects. The fasting lipid profile was evaluated within the level of total cholesterol, triglycerides, low density cholesterol and high density cholesterol in patients compared with control subjects which was dichotomy as users and non-users.

Figure 1. Association between the consumption of pork meat and faith of patients with FIS.

Table 5. Laboratory lipid profile results: comparison between patients with FIS and normal control subjects

	Groups		
Variables	Patients with FIS	Control subjects	Statistical
	(n = 231)	(n = 194)	analysis*
Trig (mmol/L)	1.65±0.66	1.70±0.79	0.526
LDL-chol (mmol/L)	3.87±0.87	3.18±0.92	0.000
HDL-chol (mmol/L)	1.06±0.25	1.19±0.44	0.000

*-test for independent samples. All values are Mean ± SD and data are based on available measurements, including triglycerides (Trig), low density cholesterol (LDL-chol) and high density cholesterol (HDL-chol).

The plasma lipid profile was similar in users and non-users in both study groups except for the level of HDL-chol, which a significant difference in the level of HDL-chol was only observed in controls subjects between users and non-users.

Table 5 shows the distribution of respondents by normal control subjects and patients in terms of obtained results of lipid profile.

When the mean values of plasma lipid profile was compared between the patients and controls, significant changes were observed regarding mean values only for HDL-chol and LDL-chol. In patients with IS, the mean level of HDL-chol tended to be higher with a significantly higher mean level than in control subjects (1.19 ± 0.44 vs. 1.06 ± 0.25 mmol/l; $p = 0.000$), whereas in control subjects, the mean level of LDL-chol tended to be higher with a

significantly higher mean level than in patients with IS (3.87 ± 0.87 vs. 3.18 ± 0.92 mmol/l; $p = 0.000$).

DISCUSSION

Analysis was done by the European Public Health Monitoring 2011 the main non communicable disease such as cardiovascular disease, type 2 diabetes mellitus, cancer, and obesity with their co-morbidities classified in category of nutrition-related disease and in what manner these represent the enormous public health problem (European Public Health Monitoring, 2011).

Recent data on the possible adverse health effect of changes dietary habits (Penelope and Santosh, 2008: 203-15) and attention on a number of factors inherent in modern diets (De Roos et al., 2001: 1233-7), including more fat in the diet (Cuevas et al., 2000: 143-8; Brown and Hu, 2001: 673-86) rather than less has brought increased attention to our work. Prospective studies of red meat consumption (including pork meat) and risk of IS (Misha et al., 2010: 2271-83; Kaluza et al., 2012: 2556-2560) have provided inconsistent results.

Consuming primarily meats with high content of fats, in particularly pork meat, that has been promoted as a model for inadequate eating in Macedonia was associated with cardiovascular disease, including stroke (Kosevska, 2004; Ejub et al., 2004: 33). However, obtained results of our two clinical studies disprove this view. To illustrate the disease effects of eating pork meat we examine the religion dietary restrictions characterized by consuming primarily pork meat in Muslims and Christian's believer from Tetovo region. In the premier study (Kamberi and Kamberi, 2012: 181-8), we measure at baseline contribution of homocysteine levels and meal with high-fat content, particularly pork meat, as variant of traditional dietary fat habits in the acute phase of first-ever ischemic stroke due to the different dietary habits. Conclusion was that meal with high-fat content did not have an impact on homocysteine levels, whereas the limiting pork consumption due religion did not have an impact on stroke frequency. Of all the patients that experienced ischemic stroke, 24.24% were users; suggestive that clear only pork consumption rate was not a risk factor which eventuates in an ischemic stroke event.

The present secondary analysis also examined adherence of their diet's effect on stroke risk by way of exception whether their meal with high-fat content, particularly pork meat, as variant of traditional dietary fat habits as a common and increasing habit may precede high blood lipid levels allusive association with atherosclerosis (De Roos et al., 2001: 1233-7), which eventually link with stroke event independently from traditional risk factors (Furie et al., 2011: 227-276; Gayle et al., 2012: 244-250). The eating habits of these two groups of participants were compared with lipid profile from a fasting blood sample measured on admission. Those who ate pork meat presented a risk of IS occurrence lower than those who never do. This report also concluded that there is insufficient evidence linking eating pork meat with meats with high content of fats and increased risk of IS (Siri-Tarino et al., 2010: 535-546).

Interestingly, Mediterranean populations referred to eat little meat than industrialized nations that eat more meat and have a low cardiovascular disease risk in comparison to their

Northern European counterparts (Vine et al., 2000: 640-4). The primary reason is the so-called Mediterranean diet (Chrysohoou et al., 2004: 152-8; Esposito et al., 2004: 1440-6).

American and European dietary guideline advocated moderate consumption of red meat, sausages and processed meat products (Lichtenstein et al., 2006: 82-96; European Stroke Organization, 2008: 457-507). And yet, from time to time choice is limited by marketable (Dietary guidelines for the Americans, 2010). The dietary guideline established by the Macedonia's Ministry of Health in this year was bearing this in mind (Macedonian Health Ministry, 2014a). This guideline recommended, for example, benefits of the Dietary Approaches to Stop Hypertension (DASH) diets.

In view of the prevailing controversy about the role of eating meat and lipid composition of the meat, no significant association was found between the risk of total stroke and consumption of proteins, including the type of fats (Rosner et al., 2010: 39-45). The results of this study were fully compatible with our obtained results. So, the fundamental difference between Muslims and Christians in Balkan was that the first one has a unified eating habits and the second one a divided different fat meat source that could be solved with their faith because doctrine was involved in their eating traditional sources (Kamberi and Kamberi, 2012: 181-8). Concretely, the characteristics weakness of the type of fats in meat (Petrovic-Oggiano et al., 2011: 5-11) and/or pork meat consumption (Kosevska, 2004; Ejub et al., 2004: 33) were identify as one of the main reasons for important effects of the rise the risk of coronary heart disease, stroke and cardiovascular disease. Traditionally, pork was eaten only by Christians and not by Muslims, but for these authors (Kosevska, 2004; Ejub et al., 2004: 33; Petrovic-Oggiano et al., 2011: 5-11) only Christian believer would be threatened.

In this study, the previously mentioned traditionalism carried out by nature of the pork consumption as traditional eating habit in feeding of subjects for religious reason do not increase risk of first stroke episode in Christians believer. FIS's disease is with high percentage of patients non-users.

The most consistent evidence for this correlation risk estimate by Chi-Square test from contingency table is provided by the comparison of disease rate between Christian's believer who eat pork meat daily or rarely, and Muslim believer, who never eat pork meat.

With regard to the age and results of lipid profile, we found that significant changes between these two groups (EG and CG) were observed regarding mean values of age, high and low density cholesterol. Our results indicate that the disease starts frequently around the sixth decade of life and were similar to finding in more homogeneous populations (Nedeltchev et al., 2005: 191-195; Allen and Bayraktutan, 2008: 105-116).

We analyze possible sex difference in patients suffering FIS because controversy persists regarding gender differences in stroke incidence. Any studies regarding sex difference in patients with IS show the greater prevalence of IS in male (Forster et al., 2009: 2428-2432) but some studies emphasize the importance of stroke in female (Roquer et al., 2003: 1581-1585; Rothwell et al., 2004: 1925-33; Reeves et al., 2008: 915-26). However, other studies do not identify gender difference (Carlo et al., 2003: 1114-9; Sturm et al., 2004: 1327-33). In the presented study we not found a significantly higher incidence of FIS in women. Age of our stroke patients was no significantly higher in men than in women, with an average difference of about one year. According to other authors, women were significantly older than men at their first-ever stroke (Rodica et al., 2009: 1032-1037).

A group authors found that the frequency of consumption of beef and/or pork, increased in the male stroke patients more than in the females (Park et al., 2003: 622-634). In our study,

pork consumption rate also was more frequent in the male stroke patients than in the females of Christian believe. Except these, all fats by nature tend to increase cholesterol, triglycerides, the low-density lipoproteins and the higher-density lipoproteins in the blood. In other words, evidence was accumulating that the high levels of low-density “bad” cholesterol can accelerate evolution of atherosclerosis (Ding, 2008: 27-31). Whereas the higher ratio of the HDL-chol was protective and, lower the cardiovascular disease risk (Cuevas et al., 2000: 143-8; Brown and Hu, 2001: 673-86) so that few studies have compared the lipid profile in patients with IS and controls, but correlation between hyperlipidemia and IS remains controversial. One reason for this was that association was not uniform across the different studies since the lipid fractions probably vary and exerted probably a different influence on stroke risk (Wannamethee et al., 2000: 1882-1888; Iso et al., 2002: 2086-2093). In several studies, IS was associated with total cholesterol (Tirschwell et al., 2004: 1868-1875; Kurth et al., 2007: 556-562), with hypercholesterolemia (Sacco et al., 2001: 2729-2735; Koren-Morag et al., 2002: 993-999), with a low level of HDL-chol (Wannamethee et al., 2000: 1882-1888; Sacco et al., 2001: 2729-2735; Tanne et al., 2001: 2892-2897; Iso et al., 2002: 2086-2093; Koren-Morag et al., 2002: 993-999), or with hypertriglyceridemia (Tanne et al., 2001: 2892-2897; Iso et al., 2002: 2086-2093). However, not all studies reported an association with total cholesterol (Amarenco et al., 2008; Zhang et al., 2012: 1768-1774), or hypercholesterolemia (Iso et al., 2002: 2086-2093), and with hypertriglyceridemia (Wannamethee et al., 2000: 1882-1888; Sacco et al., 2001: 2729-2735). Although one study was show that hypertriglyceridemia was significantly associated with cardioembolic stroke compared to controls subjects (Dahl et al., 2000: 110-117), in another report authors have reported a significant association between hypertriglyceridemia and extracranial arterial atherosclerosis, but not with lacunar infarction or cardioembolic stroke (Iso et al., 2002: 2086-2093). In one study (Cerrato et al., 2002: 653-655) there were no found statistical difference for levels of total-chol, LDL-chol and triglycerides. Similarly, like this study (Cerrato et al., 2002: 653-655) our results do not demonstrate any evidence for an association between the fractions of lipid profile and IS.

Result up until now from the meta-analysis of prospective epidemiologic studies (Siri-Tarino et al., 2010: 535-546), conclude that there was no significant evidence for concluding that dietary saturated fat was associated with an increased risk of coronary heart disease, stroke and cardiovascular disease. Similarly review affirmative participants that following the DASH diet had significantly higher HDL-chol and lower LDL-chol levels compared with the control group, but this diet did not have an impact on triglyceride levels (Gayle et al., 2012: 244-250).

From another point of view, between a numbers of environmental factors that changes dietary habits of ethnic groups in Europe (Penelope and Santosh, 2008: 203-15) and a number of factors inherent in modern diets (De Roos et al., 2001: 1233-7; Hu, 2002: 3-9) consuming primarily meats with high content of fats, in particularly pork meat, and dairy products made of it that has been promoted as a model for inadequate eating in Macedonia (Kosevska, 2004; Ejub et al., 2004: 33) and in Republic of Kosovo (Petrovic-Oggiano et al., 2011: 5-11). A high fat diet is also typical for Finland, Austria and Greece, but in comparison with France, these countries maintains a high rate of coronary heart disease, whereas yet the French have a lower rate of coronary heart disease than many other western countries (Vine, 2000: 640-4). This coincidence has given rise to the fact that unhealthy diet (The report from the United

Nations, 2011) was also not absent in Macedonia (Macedonian Health Ministry, 2004: 9-10; Macedonian Health Ministry, 2014: 1-30).

Conclusive lead of social stratification with higher unemployment rates, deteriorated and unsafe living conditions were and now considered effects of the long time transition process in Macedonia which favored change on the diets of Macedonian people.

The consequence of this modernization modality meal with high-fat content (Kosevska, 2004) and “fast food” in fast food chain (Simovska-Jarevska et al., 2013: 20-30) were cognizable a sign of westernize as well as a common and increasing habit in RM. In the investigations conducted in Macedonia, contribution of the disparity in some of the poorest regions (Kosevska, 2004; Ejub et al., 2004: 33; Simovska-Jarevska et al., 2012: 370-374), the disparities in eating habits as matter of faith (Kosevska, 2004; Ejub et al., 2004: 33; Kamberi and Kamberi, 2012: 181-8), differences in food consumption based on education and/or occupation/income in population (Simovska-Jarevska et al., 2013: 20-30), an unhealthy diet consequence of a transition in lifestyles that leads to increased risk of no communicable disease (Kosevska, 2004; Ejub et al., 2004: 33; Simovska-Jarevska et al., 2013: 20-30) from among authors were interesting and prominent, but still unconvincing. Among other things, there how both socioeconomic changes and westernization impact on the diets of Macedonian people remains unclear.

In this regard, a single report (Shukarov, 2012) explores how the transition changes were still very sensitive question. He presents from citizen's views and perceptions, effects of transition process and economic crisis in Macedonia. There was dissatisfaction, especially among young people and an overall dissatisfaction of the public with the social protection policy in the country. Apart from the problems typically attributable to the transition processes there were the overall deterioration of living conditions. The transition period additionally intensified poverty scale, the Macedonian population in general became more socially vulnerable, as the new poor (unemployed, redundant workers, internally displaced, disabled in the conflict and members of their families). The poverty has a serious impact on the health status of the population, in the case of RM specifically, on the accessibility of health services (Gjorgjev et al., 2006: 1-98). A group authors presents how availability of whole grain bread and eliminating “fast food” are intertwined with most important radical change in the food market and food production (Simovska-Jarevska et al., 2012: 370-374). They also indicate that the promotion of health through improving physical activity and dietary habits should be focused on younger age groups and adults over 50.

Data of this study noticed that the prevalence of consumers was decreased with the increasing age, which means the younger ages are more inclined toward consumption of pork meat. At the same time, in our participants of both study groups, an acceptance of westernize lifestyle was noticeable. These results were not surprising for those familiar with the Macedonian economy and was not experiencing a continuous social unrest.

Thus, in more general terms, the conclusion of our previous (Kamberi and Kamberi, 2012: 181-8) and recent study indicate that the increase risk of IS in individuals from Tetovo region comes indirectly from probability important cumulative effects of role and influence of the daily adaptation in “western” diet, and probability its effect on the major modifiable risk factors for stroke (Gayle et al., 2012: 240-250; Furie et al., 2011: 226-276), that may precede high blood lipid levels and are associated with atherosclerosis (Ding, 2008: 27-31), independently from traditional risk factors (Gayle et al., 2012: 240-250). Moreover, a more detailed description about extension of the westernize Macedonia lifestyle could not be solved

with the faith diet traditional sources and it wouldn't be a bad idea to follow other countries way of doing such.

CONCLUSION

Results of our study show difference of stroke rate hospitalization in genders that difference was paralleled by differences in age of stroke patients.

In conclusion, this controlled study show that as the age increases, frequency of patients with FIS increase at individuals from Tetovo region, while frequency of pork meat consumers decreases. Those individuals not having a different plasma lipid profile although were more expected since to use pork meat in comparison with than those who no consume pork meat. Also the analysis exposes that lipid profile was not associated with IS.

From a religious perspective, Muslims and Christian believers from Macedonia still maintain their individuality. Maybe there was a higher risk from adaptation in "western" diet and/or by the combination of multiple co-existing risk factors, above than high levels of a single factor like consuming primarily meats with high content of fats, in particularly pork meat, that has been promoted as a model for inadequate eating in Macedonia. The process by which stroke risk was induced by adaptation in "western" diet as modifiable behavior, in Macedonia needs further study.

This study recommends promoting the lifestyle and health risk behaviors among Macedonia populations because the demographic, economic and social implications of long transition period were enormous which resulted in poor quality of life and health for an average subject in Macedonia. The impact of these factors has engendered some new phenomenon, not evidence before the 90s, such as tobacco use, physical inactivity, consumption of alcohol and unhealthy diet, four primary behaviors risk factors which were consider to cause a disturbing increase in the lifestyle transition. Also, Macedonia to go by through demographic transition, participation of elderly from 65 years to increase from 7.3% in 1991 to 11.9% in 2012 year. In 2011, 27.7% of population shacks up 75 US dollars monthly, whereas data from 2013 showed a high unemployment rate (31%) from workforce (Macedonian Health Ministry, 2014: 1-30). Literature was in the consensus that respondent's education and occupation/income played a significant role in socioeconomic difference in eating habits (Simovska-Jarevska et al., 2012: 370-374). In populations' lifestyle exist serious problems and these data also provide inside into ways to shape a public health response. As a result, modernity, there's a change in eating habits between tradition and modernity; a new example of the trend nowadays was that a large number of individuals were interested to "fast food". However, a considerable number of them are engaged in health risk behaviors. We need to change the way society view and treats the westernization impact on the diets of Macedonian people.

ABSTRACT

Stroke was reported to be the second leading cause of death and the first leading cause of long-term disability in developed nations. It entails compromised brain function following a disturbance in local blood supply. Survivors of stroke present with persistent neurological defects manifested physically, emotionally, and mentally. Despite immense research, limited therapies exist. Exercise has long been known to provide neuroprotection to ischemic tissue and to improve prognosis of stroke. Early exercise in particular seems to confer neuroplasticity following stroke, mediated by mechanisms such as neurogenesis, angiogenesis, and synaptogenesis. The cause for contention, however, is determining the ideal window of opportunity to maximize the benefits from exercise therapy and minimizing the potential for secondary complications. This article seeks to shed light on some contemporary exercise-mediated therapies and the variables involved. Variables under investigation that could potentially improve prognosis in stroke patients include exercise onset, type, and intensity. Special attention is allocated to eliciting the effects of early exercise at the cellular and molecular levels with the use of human studies as well as animal models.

INTRODUCTION

Stroke is a major cause of disability and death in developed countries [1] ranking second to ischemic heart disease [2]. Surviving stroke patients present with persistent neurological defects manifested physically, emotionally, and mentally. Approximately 85% of stroke patients experience complications at the hospital, and more than half of them die as a result of complications stemming from immobility [3]. Additionally, 1/3 of patients will die from recurrent stroke within 12 months of the initial stroke, while another 1/3 will be restricted to the most basic activities of daily living (ADL) [4].

Despite immense research, limited neuro-therapies exist.

However, the potential of exercise-mediated therapy for functional recovery post-stroke is well-recognized. Exercise exacts many health benefits and shows promise in providing neuroprotection to ischemic tissue. In fact, exercise therapy is currently widely administered to post-stroke patients. Benefits of exercise in older adults, a population more vulnerable to stroke, include increased chances of survival and healthier ageing in general [5].

Additionally, studies show that training or rehabilitation induces neuroplasticity in regions surrounding the lesion site and the contralateral hemisphere [6]. Despite the prevalence of its use in therapy for stroke patients, an optimal rehabilitation method for stroke patients pertaining to exercise onset, dose intensity, and type remains to be fully characterized [7]. Although clinical research strongly supports early mobilization and training [8], some studies have demonstrated that early exercise may not be beneficial but rather exacerbate brain damage following focal brain ischemia [9-11].

Therein lies the dilemma: how early is early exercise onset in order to be deemed maximally therapeutic to stroke survivors. This review article seeks to discuss the rehabilitative capacity of early exercise in stroke patients, to navigate through the current debate pertaining to defining early in early exercise, and the potential molecular and physiological basis underlying the exercise-mediated rehabilitation post-stroke.

EXERCISE REHABILITATION TODAY

Rehabilitation today recognize that as many as 50-70% of stroke survivors suffer from motor impairments and disabilities such as muscle weakness, reduced mobility, loss of strength and dexterity, and the inability to maintain balance [12, 13]. In reflection, the aims of rehabilitation therapy enable patients to enjoy an adequate quality of life by restoring sufficient function to allow patients to perform the ADL thus maintaining a continued sense of independence [14].

Current Models of Exercise-Mediated Recovery in Clinical Setting

To achieve the most positive outcome, patients are admitted to a stroke unit as early as possible. These units stabilize the patient's medical condition, develop the optimal treatment plan, make efforts to reduce the overall death rate, and to reduce the time spent in the hospital [15]. Once stabilized, rehabilitation becomes the main focus. This process often begins 1-2

days following stroke, taking place either at an in-patient or out-patient facility, or is home-based--all of which occur under the supervision and counsel of a team of physiotherapists, psychologists, occupation therapists, and psychologists. The rehabilitative process comprises of two phases: the early acute phase and the late phase. The early acute phase is essential in reducing secondary complications and impairments while promoting independence. In the late phase, the focus shifts to preventing secondary stroke [16]. However, no process coincides without its challenges. Although contemporary rehabilitative models focus on the acute stroke period primarily to facilitate ADL and functional recovery [17], many patients stop therapy prematurely and are discharged without achieving full recovery. Consequently, almost half of these patients regress in functional mobility within a year [18].

There are many hurdles associated with identifying the optimal rehabilitative strategy for stroke patients. One such factor is the patients' poor capacity for exercise [19, 20]. These patients exert as little as 40% of the capacity of age- and gender-matched individuals with a sedentary lifestyle [21, 22]. Meanwhile, the energy requirements of these patients with hemiparetic gait is increased by 55-100% [23, 24]. Energy requirements may be even greater in patients with neurological disability due to biomechanical inefficiency. Additionally, these individuals have low endurance which can further limit their mobility [17, 23, 25, 26]. In a 50-yard ambulation task, stroke patients experienced dyspnea, progressive slowing, and reduced motor dexterity. Meanwhile, chronic stroke patients exhibited VO₂ levels half that of control individuals, levels which were only sufficient for performing basic ADL. Consequently, performing middle or upper range ADL was exhausting and often impossible. Henceforth, achieving even small gains in fitness levels translates to significant functional gains in stroke patients.

This marks the premise for developing exercise interventions of adequate duration and intensity with the correct onset to stimulate peak aerobic fitness and to facilitate recovery [22].

Clinical Evidence-Based Effects of Early Exercise on Stroke Outcome

For patients with mild to moderate disability following stroke, an early exercise intervention has shown to be one of the most effective forms of rehabilitation [27]. A large meta-review of 21 studies published by Ada et al. concluded that progressive resistance exercise <6 months post-stroke led to significant improvement in patient strength as well as level of activity. Meanwhile, only some improvements ensued in patients in the chronic phase (>6 months). It is thought that the observed difference can be attributed to a greater loss in muscle strength incurred from reduced muscle use and motor unit activity during the chronic phase [28]. This finding poses the important question of whether starting exercise rehabilitation even earlier will lead to an even better stroke outcome.

Overwhelming evidence from clinical studies indicates that exercise initiated within 30 days post-stroke leads to improved functional recovery [19]. In a study of 364 hemorrhagic stroke patients, those admitted to a rehabilitation program within 24 hours of admission performed much better on the Fugl-Myer Assessment Scale (FMA) and Modified Barthel Index (MBI) compared to their control counterparts who received standard hospital ward and internal medical treatment. The most significant gains were observed within the first month [20].

Additional evidence supporting this supposition comes from one of the first large-scale clinical studies looking at the effects of early exercise rehabilitation, AVERT (A Very Early Rehabilitation Trial). This study indicated that patients admitted to a rehabilitative program within 24 hours of stroke onset exhibited positive outcomes. Patients in both the intervention and control group were mobilized out of bed on an average of 18.1 hours and 30.8 hours, respectively, post-stroke with intensity—frequency, length, and level of activity—higher in the intervention group. Their rehabilitative therapy comprised of 10 activities including lying, activities in bed, supported sit, sitting activities, sit-to-stand, standing, early gait, advanced gait, upper-limb training, and other. Both groups received the same baseline standard care. There was no correlation between therapy dose or frequency and the number of adverse events 3 months post-stroke [29].

An additional difference observed between the two groups lay in the capacity of these patients to walk 50m unassisted: the interventional group was able to walk 50m unassisted significantly faster (3.5 days) than the standard care group (7.0 days). Furthermore, Barthel Index and Rivermead Motor Assessment measured at 3 months post-stroke associated the interventional group to better functional outcome [30].

A second study known as the Very Early Rehabilitation of Intensive Telemetry After Stroke (VERITAS) exhibited similar dramatic results when using the same protocol as AVERT (with respect to timing, nature and frequency of intervention) to treat the intervention group. Within 5 days of admission, 74% of the patients in the early mobilization group were able to walk independently, compared to 44% in the standard care group. The former group also exhibited a trend of achieving independence by 3 months with fewer medical complications after adjusting for age and stroke severity [31]. By amalgamating findings from both AVERT and VERITAS, the onset of initial mobilization post-stroke was significantly shorter (21 hrs) in the intervention group compared to its standard care counterpart (31 hrs). The early mobilization onset patients also exhibited a greater chance of acquiring independence by 3 months [31].

An additional study supporting early rehabilitation post-stroke comes from the Post-Stroke Rehabilitation Outcomes Project (PSROP) which looked at 1291 patients in six inpatient rehabilitation facilities. Findings indicated that delaying admission upon onset of stroke, moderate and severe, resulted in lower discharge functional independence (FIM) scores and increased length of stay (LOS). Consequently, the delay time between stroke onset and admission is a significant predictor of discharge total FIM score, discharge motor FIM score, discharge mobility FIM score, and rehabilitation LOS. The greatest gains in improved functional outcome were observed in the subgroup with the most severe stroke [32].

Aerobic exercise has been shown to have significant therapeutic effects in mild and moderately-impaired stroke patients [12]. It can include activities such as rowing, cycling, running, walking, and stepping. For patients with impaired balance, a stationary bike is used.

Patients unable to bear weight on an affected paretic leg are often engaged in aerobic water exercise, which provides some weight support, reducing joint impact loading, while still offering sufficient resistance [12].

A large meta-review of 151 studies published by van Peppen et al. found that the greatest therapeutic outcomes are from a combination of direct, focused tasks of sufficient intensity and early onset [27].

In summary, the discussed studies posit support for a strong association between early enrollment into a physical activity/exercise-based rehabilitation program and improved

functional outcome following stroke. In addition, very early mobilization has shown to reduce medical complications as well as the time necessary to restore functional walking capacity. Similar to early mobilization, late rehabilitation is also somewhat associated with better stroke outcome [28]. It is important to note, however, that clinical studies have many limitations and possible confounding variables. There is very limited data with regards to early exercise effects on patients with more severe stroke, as well as for all stroke patients undergoing exercise immediately following stroke onset (<18 hrs). Similarly, some very early mobilization studies have reached inconclusive results [33]. Furthermore, despite very early exercise generally being promoted [34], it remains somewhat controversial [35, 36]. With the use of animal models such as the well-established rat stroke model, it is much easier to control for variables such as stroke severity or precise location of infarct and to study much earlier exercise onset.

Effects of Late Exercise and Other Factors in a Clinical Setting

In a human clinical study applying learning-based sensorimotor training (LBSMT) beginning 6 months after stroke, improvements ensued with respect to patient independence, fine motor skills, sensory discrimination, and strength. LBSMT is a neuroplasticity-based approach comprised of progression through a set of tasks related to discriminating shapes and textures, vibrations and force, controlling force, holding and eventually moving objects all with the affected hand [15]. After 6-8 weeks, patients that were subject to great intensity of training (i.e., frequency and duration) had much better outcome than their control counterparts who experienced training of lower intensity [37]. Although late exercise is indicated to be effective in maintaining and even improving function and independence through intense LBSMT in stroke patients [37], there is an ever increasing evidence for early and intensive activity to facilitate and accelerate return to unassisted walking and functional recovery in stroke patients [30].

Depending on the onset of late exercise, human studies in general have concluded that brain injury patients can indeed reap the benefits from a late exercise regimen, although such benefits are not as great as if the exercise was started early. Additionally, delaying rehabilitation significantly increases the risks of medical complications [3]. A study supporting late exercise demonstrated that functional benefits in the late stage of recovery post-stroke do ensue learning-based therapy. Additionally, LBSMT for 6-8 weeks was associated with a non-linear positive correlation between training intensity (measured by frequency of weekly visits) and motor functional recovery [37].

TRANSLATING ANIMAL STUDIES TO HUMAN DISEASE

Clinical trials are unequivocally the ultimate translational tool despite being a challenge to design, fund, and conduct. Nonetheless, animal experiments have proven indispensable in the study of human diseases. In the scope of this article, the use of rat models in the study of human stroke treatment research represents a powerful translational variable. Rodent models permit manipulation of various variables while extending control over environmental factors,

all of which have greatly advanced our mechanistic understanding of ischemic stroke pathophysiology.

Despite this progress, gaps exist in translating animal findings to the clinic with respect to applicable therapies.

In the context of exercise-onset dependent recovery from ischemic stroke, timing is proven to be a conundrum that limits our interpretation of the vast animal studies to humans. More specifically, the precise correlation of ischemic time between human and rodents remains unknown. However, it is clear that the tolerable duration of primate and human brain ischemia is considerably longer (6-8 h) than of rats [38]. Secondly, consider that current laboratory studies utilizing rat models are often implementing post-ischemic early exercise between 24-48 hours [39-43]. There is no doubt that the implementation of exercise at 24 hours in ischemic injured rats may not be early enough to simulate human conditions, considering the significantly shorter life span of a rat. This also implicates that the critical period, time course in which the ischemic brain is most sensitive to the beneficial effects of exercise, in animal stroke studies may be different from the critical period in human stroke. Consequently, the age of the animal was found to be a key factor in discerning the neuroplasticity related molecular profile and onset of its expression, which may be an important factor to consider in the translation of these findings to humans.

CURRENT DEBATE ON THE OPTIMAL USE OF EXERCISE

How Early Is Early Exercise

Several factors impact the healing capacity of exercise as related to brain injury. Among them include onset of exercise which can have profound effects on prognosis of surviving stroke patients.

As alluded to previously, many guidelines pertaining to physical therapy and rehabilitation for stroke patients recommend early physical activity and ambulation at the least. As indicated above, clinical studies are applying therapy to patients as early as 18hrs post stroke [29, 30, 44, 45].

Concomitantly, researchers have employed animal models such as the middle cerebral artery occlusion (MCAO) rat models to assist in the delineation of the earliest time frame in which exercise therapy is beneficial rather than detrimental. The earliest documented exercise treatment for MCAO ischemic rat models is 24h [42, 46, 47]. Exercises employed include repetitive and motor skill training [42, 46, 48]. Some studies exposed animals to enriched environments constituting various physical activities [46] as well as force animals to use their impaired limb immediately following surgery [49, 50]. One study defined early training from 0-6 days [51]. Studying the therapeutic impact of various onsets of physical activity/exercise on stroke outcome is key to delineating the window of opportunity in which to reap the optimal benefits of exercise-mediated therapeutic intervention post-stroke. Needless to say, this can have profound effect on contemporary exercise-mediated treatment for patients suffering from various brain injury.

Early Exercise May Be Good or Bad

The rising interest in the potential therapeutic implications of exercise-mediated functional recovery in stroke patients has sparked the pursuit of defining the necessary time frame in which to optimize the benefits of exercise. The plethora of studies that have populated this discipline have led to conclusions short of unanimity. Although several studies have substantiated the beneficial effects of early exercise on recovery from cerebral ischemia [52-57] or hemorrhage [58] in animal models, there are some that contradict those findings by suggesting that early training exacerbates brain damage post stroke [9-11]. This section seeks to navigate through some of these studies.

Animal models are an invaluable tool used to simulate various human brain injuries. The MCAO induced ischemic rat model is one such model onto which the stroke outcome of various early training regimens is immensely investigated. In one study, animals that were administered treadmill training 24h post-surgery for one week exhibited reduced infarct volume and improved neurological function. Early treadmill training may mediate recovery of motor function by re-establishing the normal motor patterns during the sensitive period soon after brain injury [42]. Similar results were observed in the intracerebral hemorrhage (ICH) animal model that underwent early exercise training beginning 24h. These animals exhibited enhanced neurological recovery void of increases in hematoma expansion and edema volume unlike animals that underwent exercise after 1 week [59]. Consistently, forced early exercise on a running wheel led to improvements in functional outcome after focal cortical lesions with no change in lesion volume [60].

Likewise, when placed in an enriched environment 24h post-surgery, MCAO induced ischemic rats showed improved functional outcome without sustaining changes in infarct volume [46, 47].

Additionally, early exercise is shown to promote recovery from ischemic stroke in an intensity-dependent manner [61] with mild to moderate intensity proving beneficial and severe exercise intensity proving to be detrimental [62]. It is thought that a milder training intensity, as in treadmill training for 30 min per day [42], promotes reorganization of relevant cortical representation areas leading to motor functional improvements [63].

The aforementioned outcomes support early exercise as therapeutic to recovery from ischemic brain injury in an intensity dependent manner.

Early exercise following cerebral ischemia may not be entirely ameliorating. Some studies have labeled a period immediately after brain injury (0-6 days) as the early phase.

The early phase was identified as a vulnerable period; henceforth, early physical activity implemented here produced a negative outcome in functional recovery, lesion volume, and lesion-induced up-regulation of plasticity-related proteins [49, 64-66]. Additionally, a number of studies have demonstrated use-dependent exacerbation of brain damage in animals with unilateral lesion to the forelimb representation area of the sensorimotor cortex. In one such study, the unaffected limbs of such rats were immediately immobilized for 14 days following cerebral damage to force the overuse of the affected limb. These animals exhibited the largest behavioral deficits and the longest recovery period compared to when the impaired limb was immobilized. Meanwhile, the latter condition displayed only slightly larger and longer-lasting behavioral deficits [50]. In addition to slowing functional recovery, forced overuse of the impaired forelimb for 7 days resulted in expansion of the lesion and compromised functional recovery [49]. Even without forced use of the impaired limb, simply exposure of MCAO

induced ischemic rats to an enriched environment and administration specific training 24h post-surgery was sufficient to exacerbate cortical tissue loss [64] thus suggesting that perhaps early training may indeed exacerbate brain damage [49, 50, 64].

Nonetheless, these studies stress the onset-dependent role of early exercise in stroke outcome, henceforth, placing importance on deciphering the confines of the window in which physical activity is beneficial rather than detrimental to ischemic tissue and subsequent functional recovery and rehabilitation.

Late Exercise in Rat Models

As in the case of early exercise mediated therapy, effects of late exercise therapy on various brain injury animal models pose similar extent of diverse outcomes. Take for instance the study that administered treadmill training to animals one week after MCAO-induced ischemia; no significant changes in infarct volume or neurological function was noted when compared to spontaneous recovery [42].

Additionally, when animals were forced to overuse their afflicted limb a week after lesion to the representative sensorimotor cortex, impaired recovery ensued although without any change in lesion volume [49].

On the other hand, delayed voluntary exercise following TBI (14-20 days) was characterized by up-regulated BDNF and improved cognitive function [51]. Up-regulation was also evident in downstream effectors of BDNF in both the dorsal hippocampus and cerebral cortex [51, 67-69].

MOLECULAR AND PHYSIOLOGICAL BASIS OF EARLY EXERCISE-MEDIATED RECOVERY

Neuroprotective Capacity of Early Exercise and Its Potential Role in Rehabilitative Functional Recovery

To understand how early exercise can potentially mediate or hinder recovery at the molecular and physiological level, a brief description of the ischemic cascade characteristic of stroke as well as TBI is warranted. Despite the difference in their initial insults, TBI and stroke share similar mechanisms that underline their pathophysiology such as excitotoxicity, oxidative stress, ROS, apoptosis, and inflammation [70]. Henceforth, TBI studies have been invaluable to advancing our understanding of effects of early exercise on stroke outcome and vice versa. The ischemic cascade ignited by stroke onset, a process similar to TBI, is a highly complex mechanism. Depending on the severity of the ischemia, brain cells may respond differently. However, despite this variation, there is a general process that all vulnerable brain cells undergo.

Recall that neurons in the ischemic core undergo apoptosis; however, it is the vulnerable neurons/tissue of the peri-ischemic core area (the penumbra) that undergo the aforementioned reversible debilitating energy consuming metabolic alternations. In agreement, this region is marked by elevated glucose metabolism that can last up to 6 h upon reperfusion [71].

Henceforth, the vulnerable penumbra can be potentially rescued through neuroprotective therapies which is the basis for rehabilitation.

Currently, a clinically effective neuroprotectant is yet to be uncovered, although exercise-mediated recovery is a frequent recourse. The rehabilitative capacity of exercise training on stroke patients is widely recognized and is applied in many physical therapy programs today. As previously eluded to, many such guidelines recommend early physical/exercise therapy. However, as seen in the previous section, the parameters under which early rehabilitative exercise is deemed maximally neuroprotective and functionally beneficial to stroke patients is yet to be characterized. This section seeks to briefly describe the ischemic cascade characteristic of stroke and the potential influence of early exercise on the cascade.

Metabolic disorder. From a metabolic point of view, the immediate repercussions of oxygen deprivation incurred in acute stroke is impaired aerobic mitochondrial oxidative phosphorylation of glucose, the primary energy source for neuronal activity.

Hereafter, surviving brain cells respond by increasing anaerobic glycolysis (hyperglycolysis), a pathway involved in the initial catabolism of glucose [72, 73]. Hyper-glycolysis is reflected in elevated levels of its key enzymes [74] such as phosphofructo-kinase (PFK), lactate dehydrogenase (LDH), and phosphorylated adenosine monophosphate kinase (pAMPK) as well as up-regulation of glucose uptake transporters 1 and 3 (GLUT1 and 3) [75]. Hyper-glycolysis also contributes to metabolic acidosis via lactate accumulation, a by-product of anaerobic glycolysis [76]. Meanwhile, the mitochondria reacts to this hypoxic crisis by increasing the activity of the rate-limiting electron transport chain (ETC) enzyme cytochrome c oxidase (CcO). Consequently, the mitochondrial membrane potential is hyperpolarized to levels that support non-physiological ROS production upon reperfusion [77]. ROS production has shown to cause cellular damage and death in cerebral ischemia and reperfusion [77]. Henceforth, conditions that support ROS production is not a cultivating environment for vulnerable brain cells [11]. Adding to the metabolic disarray, brain cells exhibit uncontrolled energy consuming activity of ion pumps. This facilitates a change in membrane potential supporting liberation of excitatory neurotransmitters such as glutamate [73, 78]. In essence, ischemia brought about by various brain injuries including stroke, is characterized by altered metabolism wherein energy supply is compromised despite an increased demand for it. This creates energy imbalance apt for oxidative stress leading to neural damage and loss-of-function [11].

Metabolic response to early exercise. It is thought that perhaps conditions that exacerbate the hyper-metabolic milieu characterized in the early ischemic period of stroke, such as physical activity and exercise, may have negative effects on the vulnerable penumbra. Consider that PFK-1, a key AMP-activated glycolytic enzyme isoform found in neurons and astrocytes [79], is increased in response to exercise. Likewise, the active form of AMPK was also found to be increased following exercise thus indicating that exercise drives catabolism to meet elevated energy demands [73]. Furthermore, subjecting animals to exercise training [80] or simply exposing them to enriched environments [81] was sufficient to induce angiogenesis, thus exemplifying the body's need to meet increased energy demands. Clinical studies have also established a significant increase in energy demand to sustain the hemiparetic gait of stroke patients [23, 24]. Henceforth, animals forced to use their impaired limb during the early ischemic period, which is marked by hyperactivity in the already vulnerable penumbra, may further tip the energy balance toward a state of deficiency. This sets the stage for transient episodes of hypoxia and reserved recovery [82-84].

The associated metabolic and neurochemical alterations following injury hinders exercise-induced neuroplasticity-associated molecular changes [51]. Eluding to this, cortical stimulation post-TBI elicits a metabolic response that may further increase cortical degeneration [85]. This finding posits that the brain may be undergoing metabolic changes during the first week post-injury, which can strongly affect the outcome of exercise-mediated therapies [86-88].

Henceforth, immature onset of exercise can divert energy stores inappropriately from the much needed production of synaptic plasticity-related molecules to meet metabolic demands of exercise on an already energetically compromised brain. Exercise increases energy demands (primarily in the hippocampus, motor cortex, and striatum) [89], regional cerebral blood flow [90, 91], and extracellular lactate [92].

BDNF signaling pathways. The resulting energy imbalance facilitates the activation of various brain cell death pathways as well as regenerative efforts following stroke. Neurotrophic factors play a key role as neuroprotectants after cerebral insult. Among them include nerve growth factor (NGF) and brain-derived nerve growth factor (BDNF) both of which promote cell growth and enhance neuronal activity [93, 94]. Although a growth factor, midkine has neurotrophic properties implicated in repair of several tissues and found to be expressed in the early stages of cerebral infarction [95].

The BDNF signaling pathway is thought to be a key mediator of angiogenesis [96], neurogenesis [97, 98], and synaptic plasticity [99] all the while serving as a neuroprotective agent [100, 101]. Additionally, this pathway is known for inhibiting the pathological processes of neurotoxicity, apoptosis, and inflammation [102]. In other words, BDNF plays a critical role in post-stroke recovery. Despite this, the effects of stroke on BDNF production has not been completely delineated. Studies indicate an increase in BDNF production at the infarct and peri-infarct sites at least a week following stroke [103, 104]. Aside from neurons, BDNF is also produced by non-neuronal cells such as endothelial cells of microvessels, microglial cells, and astrocytes in the ischemic brain. Additionally, BDNF production by these non-neural cells is positively correlated with infarct size [105].

The signaling pathway involving BDNF is quite diverse. Mature BDNF is cleaved from proBDNF by tissue-type plasminogen activator (tPA). This change allows BDNF to bind to the TrkB receptor enabling the activation of many intracellular signaling pathways including the Ras/extracellular signal regulated protein kinase (ERK), the phosphatidylinositol-3-OH (PI3K)/AKT kinase, and the Ca^{2+} activated kinase (CaMKII) pathways [106]. These pathways converge to manipulate CREB production, phosphorylation, and function [107] which in turn affects transcription of cell survival genes. The AKT pathway indirectly manipulates CREB by deactivating its antagonist transcription factor FOXO3 known to induce transcription of apoptotic proteins [108], henceforth indirectly promoting cell survival [109] (Figure 2).

Another downstream effector of the BDNF-TrkB signaling pathways is synapsin I, a synaptic trafficking protein expressed in axon terminals, involved in the facilitation of neurotransmitter release, axonal growth, and the maintenance of synaptic connection [110, 111]. Its synthesis and phosphorylation is affected by CaMKII and ERK signaling (Figure 2). ICH studies have indicated that the BDNF-TrkB signaling pathway is activated in the perihemorrhagic area. Significant increases were observed on day 7 which subsided close to normal levels by day 14. This suggests that the BDNF-TrkB signaling pathway may be

involved in the brain repair process, although levels present maybe insufficient for complete functional recovery [112].

BDNF-induced neuroplasticity. Exercise is neuroprotective and can induce neuroplasticity in many CNS disorders including stroke [113, 114]. It is linked to slowing cognitive decay [115], neuronal protection against ischemia [53], enhanced neurogenesis [116], and improved learning capabilities [116, 117] making exercise a viable candidate for improving prognosis in ischemic brain injury [118]. The benefits incurred through exercise are strongly linked to increases in neurotrophic factors such as BDNF [56]. Increases are seen throughout the brain, especially in the hippocampus and posterior cortex [119]. It is thought that persistent BDNF expression is crucial for recovery from ischemic/hemorrhagic stroke, the expression of which can be prolonged through exercise. In fact, exercises such as treadmill training have shown enhanced and prolonged activated BDNF-TrkB pathway in the peri-hemorrhagic areas of ICH-induced rats, suggesting the important role of rehabilitation by treadmill exercise [112]. Increases in BDNF are attributed to enhancement of functional recovery in MCAO animals exposed to enriched environment and exercise [120]. Consistently, voluntary wheel running exercise increased downstream effectors of BDNF such as PI3K, PKB/AKT, CREB, and TrkB in the hippocampus [121].

Exercise has also shown to increase the activity of tPA which is responsible for the conversion of proBDNF to mBDNF. This became evident when inhibited tPA activity reduced exercise-induced effects of BDNF. Subsequently inhibition of TrkB receptor and its downstream signaling effectors ERK, Akt, and CaMKII followed. Furthermore, exercise-induced expression of plasticity markers synapsin I and growth-associated protein 43 (GAP-43) were also reversed.

This finding implicates the hippocampal plasticity effects of exercise to BDNF processing and henceforth, TrkB signalling [106].

It is well known that endogenous BDNF and its downstream effectors are up-regulated and functional recovery enhanced post-TBI when running wheel exercise was delayed for 14 days. However, when exercise was administered sooner (0-6 days) post-TBI, endogenous BDNF levels were reduced and associated cognitive impairment were observed. All the while, sham animals exhibited hippocampal BDNF upregulation proportional to the amount of exercise [51]. In addition to reduced BDNF expression, pCREB expression was also reduced and associated impaired learning ensued with early voluntary exercise (0-6 days) [65]. It is possible that the stress of increased metabolic demand imposed by exercise may have adverse effects early after brain injury by further injuring the already compromised tissue.

According to amassing literature, exercise-induced changes in gene expression are perpetuated via modulation of the BDNF system, promoting cell survival and inhibiting apoptosis as discussed previously. Other interactions that converge onto this pathway include the Ca^{2+} activated kinase, CaMKII, which is observed to be up-regulated during acute exercise [122]. Additional up-regulated genes in rats that underwent voluntary running exercise include those involved in synaptic trafficking (syntaxin, synapsin I, and synaptotagmin), neurotransmitter systems, and other signal transduction pathways [122]. Exercise-induced BDNF-TrkB interaction also activates the MAP-K cascade which leads to downstream phosphorylation of CREB [123] and protein synapsin I [124-126]. Among its many roles, CREB induces transcription of target genes, including BDNK [123] related to long-term plasticity [127] and memory [128].

Exercise and Neuroplasticity: Synaptogenesis, Neurogenesis, and Angiogenesis

As eluded to in previous sections, exercise promotes changes in the brain at a neuroanatomical level. Evidence from both human and animal studies converge to suggest that physical exercise promotes neuroplasticity in certain areas of the brain [129]. In the context of ischemic stroke, recovery of motor function involves relearning of motor skills which is a neuroplasticity-mediated process [130]. This recovery process can occur spontaneously post-stroke but can also be enhanced with appropriate rehabilitation [63, 131, 132].

This section will explore the response to post-ischemic stroke with respect to neuroplasticity and the potential role of exercise as a facilitator.

Neurogenesis. Animal studies have established that voluntary aerobic exercise can induce formation of new neurons within the hippocampus of adult mice concomitant to enhanced learning.

This process, occurring primarily in the subventricular zone (SVZ) and subgranular zone (SGZ) of the hippocampus of the adult brain [133, 134], is hampered in the elderly who are a highly susceptible to stroke [135-138].

In addition to its preventative capacity, exercise can also reverse deleterious consequences of aging [134, 139]. Like exercise, environment enrichment, growth factors, and even pathological process such as ischemic stroke can induce neurogenesis. Experimental stroke in animal studies have shown newborn neuron migration into ischemic brain regions. Similarly, stroke patients have expressed markers associated with newborn neurons in the ischemic penumbra preferentially near the vicinity of blood vessels [140].

As discussed previously, trophic factors are key players in adult neurogenesis. In addition to BDNF, notable trophic factors include basic fibroblast growth factor (bFGF-2), epidermal growth factor (EGF), insulin like growth factor I (IGF-I), and vascular endothelial growth factor (VEGF). For instance, intraverebroventricular administration of BDNF increased neurogenesis in the adult olfactory bulb [141] and striatum [142].

In agreement, BDNF knockout mice failed to show enhanced neurogenesis following environmental enrichment [143]. As seen with the BDNF signaling pathway, exercise is also associated with increased genes expression of FGF [68, 144] and NGF in the hippocampus [145].

Angiogenesis. Angiogenesis and neurogenesis are closely associated processes [146-149]. For instance, it has been demonstrated that new cells of the dentate gyrus associate with blood vessels [146] and respond to vascular growth factors such as VEGF [150, 151]. Additionally, increased adult neurogenesis [152] and a reversal of aging-associated decrease in neurogenesis [153] was observed with peripheral infusion of IGF-1 [145].

Like neurogenesis, angiogenesis can also be induced in the CNS by hypoxia and ischemia seen in stroke [154]. It is well established that physical exercise increases angiogenesis throughout the brain [155-158] which is proposed to be mediated by IGF and VEGF. Running exercises enhance IGF gene expression [159, 160], increase serum IGF [161] and VEGF [162].

Consistently, inhibition of VEGF and IGF-1 failed to show enhanced neurogenesis observed with running [145, 162, 163].

Synaptogenesis. The penumbra is the site of active structural and functional remodeling. It is characterized by factors that induce axonal sprouting [132, 164, 165] and support elaboration of dendrites and spines [166, 167]. Positive factors involved in this rewiring process include: glial-derived synaptogenic thrombospondin 1 and 2 [168] and growth-related proteins such as GAP43, mArCKS, CAP23 and growth factors [169-171]. This process is regulated by factors that inhibit outgrowths such as extracellular matrix factors NOGO [172-174], chondroitin sulphate proteoglycan 64, ephrin A5, semaphorin 3A and neuropilin 1, and EPH receptors and ligands [175]. Interestingly, expression of these factors are temporally related such that growth stimulatory factors precede inhibitory factors after stroke [175].

Window of opportunity for neural plasticity in the post-ischemic brain. As eluded to previously, neuroplasticity can occur spontaneously following an injury as seen when the corresponding cortical area of a transected median nerve of adult owls or squirrel monkeys was completely occupied by new and expanded representations of surrounding skin fields [131].

Such cortical reorganization is no exception following stroke. For instance, adult mice in which focal ischemic stroke was induced in the forelimb sensorimotor cortex showed a re-emergence of forelimb-evoked depolarization from surrounding peri-infarct motor/hindlimb area as well as from the distant posteromedial retrosplenial cortex [132].

The existence of a critical period during which the brain is sensitive to exercise rehabilitation is a recurrent theme throughout this article. This concept was eluded to in the previous section pertaining to onset-dependent effects of exercise in animal models. Recall that proteins regarded as positive factors for neuroplasticity such glial-derived synaptogenic thrombospondin 1/2 [168] and proteins that promote synaptogenesis such GAP43 [170], CAP23 and mArCKS were highly expressed post-stroke. Meanwhile, Nogo-A [172], MAG, semaphorin 3A, CSPG [176], and neurocan [177] are thought to be factors that inhibit axonal outgrowth and sprouting. Taken conjunctively, it is hypothesized that an interplay between positive and negative factors that either promote or discourage neuroplasticity, respectively, might be an important determinant of this critical period.

CONCLUSION

Exercise-mediated rehabilitation therapy is unequivocally beneficial in the recovery of stroke survivors. However, the benefits incurred are variable in the scope of early exercise-mediated therapy. Animal studies utilizing various stroke models, particularly the MCAO rodent model, have investigated this phenomenon in functional recovery and have concluded that benefits can range from significant to detrimental. These findings have fueled the proposition of underlying time-dependent factors that may negatively affect the beneficial outcomes of exercise following stroke. Animal studies have focused on deciphering the underlying mechanisms. Molecular perspective under study include the influences of the changing metabolic milieu following stroke, termed as metabolic disorder, and the dynamic signaling pathways involved in neuroplasticity, the cornerstone of functional recovery. Understanding the time-dependent interplay between these processes can perhaps provide a clue to the nature of the onset-dependent benefits of exercise and therefore advance the field of exercise rehabilitative therapy.

Chapter 71

STROKE AND TRAUMATIC BRAIN INJURY

Panagiota Korenis, MD

Assistant Professor
Bronx Lebanon Hospital
Albert Einstein College of Medicine, Bronx, NY, US

STROKE

Anterior Circulation

- Carotid arteries (most atherosclerotic disease occurs at the bifurcation of the common carotid and internal/external carotid artery)

Posterior Circulation

- vertebral artery turns into the basilar artery
- infarction at posterior inferior circulating artery (PICA) results in Locked in Syndrome
- duret hemorrhage: can be seen with trauma, herniation. Consequence of perforating arteries that feed the brainstem

Circle of Willis

- communication between anterior and posterior circulation
- Posterior Communicating Artery: CNIII affected

High Yield Stroke Facts

- Worst risk factor: age

- Other risk factors: hypertension, elevated homocysteine, CRP (inflammation)
- Treatment: intravenous tPA within 3 hours (contraindication: if on blood thinner, seizure at onset, uncontrolled hypertension)
- Reduce risk of stroke: hypertension meds, aspirin, clopidogrel, dipyridole with aspirin, statins, coumadin, stents (more than 70% occlusion will benefit from endarterectomy)
- Major depressive disorder post stroke: 10%, 30-50% will present with some symptoms of depression
 - Treatment for major depression post stroke: Nortriptyline
- Mechanism of cell death in stroke: necrosis

DEFICITS IN STROKE

Motor

- Hemiparesis contralateral to lesion
- Anterior cerebral artery (ACA) stroke: will predominantly affect distal limbs
- Middle cerebral artery stroke (MCA): will predominantly affect face, proximal limbs

Sensory

- (Spinothalamic- pain, temperature, lemniscal- proprioception, vibration) sensory pathways merge in the thalamus
- hemisensory loss contralateral to lesion
- MCA stroke: face, upper limb sensory affected
- ACA stroke: lower limb sensory

Visual

- Homonymous hemianopsia
- Pontine stroke: eyes will deviate toward the hemiparesis
- MCA, PCA (supplies temporal and occipital lobes) stroke: eyes will deviate toward the lesion

Behavioral

- Arousal mediated by reticular activating system
- Left middle cerebral artery (MCA) stroke: loss of language
- Right MCA stroke: loss of visual-spatial orientation, neglect left side
- Brainstem, thalamic strokes: loss of arousal

STROKE SYNDROMES

Anterior Cerebral Artery (ACA) stroke

- Symptoms: contralateral leg is more affected than arm which is more affected than face

Middle Cerebral Artery (MCA) stroke

- Symptoms: contralateral hemiparesis, hemisensory loss, eyes deviate towards lesion, contralateral homonymous hemianopsia

Common or Internal Carotid Artery (ICA) stroke

- Symptoms: contralateral homonymous hemianopsia, unilateral: alexia without agraphia
- Vertebral/basilar stroke
- Symptoms: no cognitive impairment, aphasia or visual deficits

Midbrain Stroke (Weber's)

- Symptoms: contralateral hemiparesis, CN III nerve palsy

Pons Stroke

- Symptoms: contralateral hemiparesis, homonymous hemianopsia, eyes deviate toward the paralysis

Lateral Medullary Stroke (Wallenberg)

- Symptoms: damage to CN V, VII, IX-X nuclei, no hemiparesis

Posterior Inferior Cerebral Artery (PICA) Stroke

- Symptoms: Horner syndrome (miosis, ptosis, anhydrosis), palate paresis, dysarthria, hoarse voice, trouble swallowing, numb face, no hemiparesis

Locked in Syndrome

- Symptoms: anarthria (inability to speak), quadriparesis, preserved cognitive capacity, vision, hearing, ocular movements
- Mechanism of action: infarction to base of Pons (spares CN III, IV, VI, reticular activating system)
- EEG: normal, no problems with thalamic-cerebral connections
- Remember: they have capacity

Vascular Dementia

- Abrupt onset, Step wise deterioration
- Symptoms: dysarthria, gait impairment, pseudobulbar palsy

Transient Ischemic Attack

- Episode lasts less than 24 hours

Anterior TIA: carotid origin

- Symptoms: amaurosis fugax (transient blindness in one eye), hemiparesis

Posterior TIA

- vertebral or basilar origin
- Symptoms: nystagmus, ataxia, diplopia, transient global amnesia (anterograde, several hours, fully alert, cannot learn new facts, disoriented, intellect, general knowledge and personal information intact)

TRAUMATIC BRAIN INJURY**Basics**

- Most susceptible to injury: inferior frontal and temporal lobes
- Coup injury: an injury at the site of impact
- Contre coup injury: an injury opposite from impact site

Epidural Hematoma

- Location: build up of blood between bone and dura

- Most common cause: middle meningeal artery tear from skull fracture
 - Symptoms: loss of consciousness followed by a period of lucidity with rapid deterioration following
- On CT scan: convex in shape

Subdural Hematoma

- Commonly presents in: chronically ill, elderly, alcoholics (alcohol puts wear on vessels, makes them susceptible to shearing), Coumadin use
- Location: between dura and arachnoid matter
- Most common cause: bridging veins are torn
- On CT: crescent in shape

Subarachnoid Hemorrhage

- Most common cause: tonsillar herniation
- Symptoms: “worst headache”, high intracranial pressure, rapid decompensation
- On CSF: xanthochromia (yellow color in CSF because of hemoglobin breakdown)

Transtentorial Herniation

- Mechanism of action: compression of reticular activating system, CN III compression
- Symptoms: coma

	Bulbar palsy	Pseudobulbar palsy
Cause:	polio, ALS, MG	TBI, ALS, MS, CVA
Symptoms:	no gag reflex, respiratory problems	hyperactive gag, no resp probs Emotional lability
Origin	lower motor neuron	upper motor neuron

Normal Pressure Hydrocephalus

- Symptoms: dementia, incontinence, gait apraxia (symptom most quick to improve and most noticed symptom)⁹
- On MRI: expansion of lateral ventricles, no cerebral atrophy
- Treatment: ventriculoperitoneal shunt

Creutzfeldt-Jakob Disease

- Symptoms: myoclonus, personality change (1st symptom), dementia, rapid course, Fatal

- Mechanism of action: prion infection (protein, no RNA or DNA) -> spongiform encephalopathy
- Prions are infectious and can be transmitted through various sources including: EEG electrodes, brain biopsy, cornea transplant, cannibalism (kuru)
- On EEG: periodic or burst suppression pattern
- In CSF: 14-3-3 protein (4)

Subacute Sclerosing Panencephalitis (SSPE)

- Symptoms: onset in childhood, reaction to measles, rapid, fatal
- In CSF: anti-measles antibodies
- On EEG: periodic or burst suppression pattern

Wernicke (reversible)-Korsakoff (irreversible)

- Symptoms: anterograde amnesia (thiamine deficiency – petechial hemorrhage into the limbic system), nystagmus, ataxia (atrophy in cerebellar vermis), confabulation
- Causes: alcoholism, nutritional deficiency of thiamine, bariatric surgery
- Treatment: thiamine replacement (remember to give thiamine first, glucose second)

ABSTRACT

The cognitive rehabilitation of stroke often improves executive functioning through repeated and systematic training of memory and attention exercises, for which virtual reality may be a valid approach. Several devices have been used as visual outputs, foremost Head Mounted Displays (HMDs) and desktop screens. HMDs are usually more immersive than screens. However, they present several shortcomings for widespread use. The aim of this study was to assess the prospect of opting for screen displays as an alternative to HMD within virtual reality (VR) based applications to rehabilitate memory and attention impairments in stroke patients. 17 stroke patients with memory and attention deficits were recruited from the hospital *Centro de Medicina da Reabilitação do Alcoitão*, and randomly assigned to two different groups: a) HMD-based VR; and b) desktop screen-based VR. The patients in both groups underwent a 9-sessions virtual reality (VR) training programme with memory and attention exercises. Patients were assessed before and after the VR training sessions with the Wechsler Memory Scale for memory and the Toulouse-Piéron for attention functioning. The results showed increased working memory and sustained attention from initial to final assessment regardless of the VR device used. These results suggest better functional independence following VR-based intervention and support the use of non-expensive displays as an alternative to high-end setups commonly used in VR applications devised for rehabilitation purposes.

INTRODUCTION

Stroke is a major cause of death in the developed countries and can result in severe cerebral lesions, which are accountable for motor disabilities and cognitive impairments, resulting in personal, professional and social dysfunctions (1). Most of the impairments reveal themselves in the form of attention and memory deficits that often compromise patients' daily life activities. Therefore, an effective approach devised to rehabilitate these functions should focus on exercising daily life activities through systematic and regular training (2).

In this context, there is much ongoing research to assess the role of neuropsychological rehabilitation in cognitive and motor recovery. The most widely known approaches for cognitive rehabilitation are function-based approaches for neuro-rehabilitation since these are focused on a specific cognitive or motor domain (3). Repetitive practice is also an important aspect in motor and cognitive training, as it improves performance in disabled patients (4).

Exercises devised to rehabilitate motor disabilities or cognitive impairments should observe rehabilitation's trinity: repetition, feedback and motivation (5-8). As an attempt to boost these aspects, virtual reality (VR) exercises are now considered a sound option. VR offers the possibility of endless repetition, providing visual, auditory and haptic feedback; and, because VR platforms are usually perceived as a game, patients are engaged, driven and, as a result, motivated by the exercise (6). In fact, according to Cirstea and Levin (7-8), in a virtual environment training exercises can be considered as more engaging and motivating than the traditional approach.

Also, some authors (e.g., 8) have argued that using VR applications in rehabilitation may benefit training purposes, mainly through the 3D spatial correspondence between movements in the real world and movements in the virtual worlds, which may facilitate real-time performance feedback. While repeating the exercises, patients' senses are provided with feedback on their performance, which can improve it further.

VR therefore seems to promote a more intensive and program-supportive approach to the execution of exercise, providing appropriate feedback to the patient. Also, exercises may be displayed with an adaptable degree of difficulty, making possible the use of non-invasive forms of physiological monitoring. VR, in addition, offers therapists the ability to individualize treatment needs, while providing the opportunity for repeated learning trials and the capacity to gradually increase the complexity of tasks while decreasing therapist support and feedback (9). VR is thus a promising response to current trends towards shorter hospitalization and foster homecare periods (10).

Motor aspects of using VR environments have also been studied. A study comparing movements performed by participants with hemiparesis with virtual objects in VR and real objects in real environments found no differences between the movements performed in VR and real environments, suggesting that this VR technique can be an effective training for rehabilitation (11). Other studies (12) compared training a specific function (making a hot drink) in stroke patients in a real-world vs. virtual world setting. Results suggested that virtual applications can be used for rehabilitation of stroke, but the neural mechanisms underlying performance in a virtual world can be different from those in real-life situations. For example, real-world performance was associated only with motor planning, whereas in a virtual world performance was more associated with praxis. Moreover, a study of arm and trunk movements with kinematics in a sample of stroke patients with hemiparesis found results in

line with previous studies and supporting the effectiveness of VR for clinical interventions with these patients (13).

Typically, VR may be experienced using one of following types of settings: (a) desktop personal computer (PC); (b) workbench; (c) CAVE (CAVE Automatic Virtual Environment), (d) HMD (Head Mounted Display) and (e) screens. PC, workbench and CAVE are usually neglected in rehab studies. On the workbench, immersion and presence levels are reduced and the CAVE represents a financial investment difficult to meet by the majority of research groups. Consequently, HMD and screens are the most currently used displays. The HMD, when associated with a tracking system, allows a 360-degree field of view and 3D stereoscopy, which is considered to be responsible for its effectiveness on immersion. On the other hand, most HMDs are heavy, expensive and, when used for a long time, may cause retinal strain. Screens allow the participation of more than one participant at a time and are not as intrusive as HMDs. However, and because the field of view is limited to the projection area and the tracking system is missing, screens are usually considered to be less immersive than HMDs.

Although the use of VR devised to rehabilitate motor and cognitive impairments is being studied intensively, there is no agreement regarding the best way to engage stroke patients in VR exercises. Thus, the main purpose of this study was to compare memory and attention outcomes between stroke patients in a VR-based training program using either HMD or PC-screen displays.

METHODS

17 stroke patients ($M_{age} = 51$ years old; $SD_{age} = 14$ years; 10 males) with memory and attention deficits were recruited from the rehabilitation hospital *Centro de Medicina da Reabilitação do Alcoitão*. All patients had more than 12 years of formal education. Exclusion criteria were:

- More than 6 months after stroke episode (Figure 1);
- Comorbidity of language disorders;
- Dementia;
- Other previous psychiatric disorders that may have an impact on memory and attention, such as drug addiction behaviors or severe depression.

Participants were randomly assigned to the desktop VR experimental group ($n = 9$; 4 males; $M^{age} = 55.56$ yrs; $SD^{age} = 8.91$ yrs; months since injury, $M = 2.89$; $SD = 3.18$) and the HMD experimental group ($n = 8$; 6 males; $M^{age} = 45$ yrs; $SD^{age} = 16$ yrs; months since injury, $M = 3.5$, $SD = 1.07$). There were no significant differences in gender, age, years of education, and time since injury between these two groups (all p 's $> .05$).

Figure 1. Time since injury.

Measures

Each patient was assessed through a brief screening test, the Mini Mental Examination Test (14) in a version validated for the Portuguese population by Guerreiro and collaborators (15). Memory and attention deficits were considered to exist when Z scores in memory and attention subscales were 2 SDs below the normative value.

During the neuropsychological intervention, our main concern was to stimulate and assess memory and attention abilities, since these are important components of executive functioning. Therefore, each patient was assessed before and after training with the Wechsler Memory Scale – WMS-III (16) and the copy part of the Rey Complex Figure test – RCF (17) for neuropsychological evaluation of memory, and the Toulouse-Piéron test – TP (18) for attention and concentration abilities.

Procedure

This study was carried out at the Psychology Department of the *Centro de Medicina de Reabilitação de Alcoitão*, Lisbon, Portugal. Patients performed a variety of cognitive exercises; either on a HP Intel® Core™2 Quad Processor Q6600 PC equipped with a GeForce GT 220 and a 21'' Asus VE228D screen display (1680 X 1050 pixels of screen resolution) (screen condition), or on the same PC, but plugged to a HiRESeMagin Z800 HMD (HMD condition).

The VR environment for cognitive exercises was developed by our team using Unity 2.5 (Unity Technologies™) and consisted of a small town with a 2-room apartment and a minimarket in the vicinity. The interaction with the VR environment was performed using the left mouse button to move forward and the right to move backwards. The space key on the keyboard was configured as an action button, to grab the objects and interact with virtual objects. The patient's avatar was spawned in the apartment's bedroom, from where they accomplished each session tasks by moving towards the final goal described below. The therapist's role was to explain sessions' procedures and to assess their outcome.

All patients participated in 12 sessions (one session per week). In the first session, memory and attention tests (WMS-III, RCF and TP) were applied. In the second and third sessions, patients acquired computer interaction skills on a training platform. The next nine sittings were used for cognitive training through the VR exercises and final assessment.

Cognitive training consisted of personal orientation tasks, such as the execution of daily living activities of morning hygiene, meal preparation and dressing (i.e., choosing the right clothes to wear), as well as working memory tasks (i.e., buying several items with a certain amount of money), recognition memory tasks (i.e., recognition of outdoor advertisements), visuospatial orientation tasks (i.e., finding a different way to the minimarket) and selective attention tasks (i.e., finding a yellow dressed virtual character) . In the last session memory and attention tests were again applied. An example of these tasks can be found below (Figure2).

Figure 2. Example of the VR training tasks. The top panel shows personal orientation tasks, the mid panel is for working memory, whereas visuospatial orientation and selective attention tasks are illustrated on the bottom panel.

RESULTS

We tested the effect of type of display with repeated measures ANOVAs with one within-subjects factor (before intervention vs. after intervention) and one between-subjects factor (HMD vs. desktop screen).

As regards memory, we found a main effect of evaluation (pre vs. post-training) on both the WMS ($F(1, 16) = 12.491$; $MSE = 117.813$; $p < 0.01$) and the RCF ($F(1, 16) = 8.676$;

$MSE = 19.709$; $p < 0.05$), showing a significant increase in both WMS scores ($M = 85.71$; $SD = 3.89$ vs. $M = 98.94$; $SD = 3.99$) and RCF scores ($M = 11.41$; $SD = 1.83$ vs. $M = 15.77$; $SD = 2.49$) from initial to final assessment. However, no significant interaction effects were reported between factors (both p 's > 0.05) in either the WMS or the RCF assessments (Figure 3), which indicates that the cognitive improvement did not depend on display type.

Likewise, we found a main effect of evaluation in the TP test ($F(1, 16) = 15.935$; $MSE = 542.598$; $p < 0.01$), indicating that sustained attention increased from initial ($M = 75.69$; $SD = 10.83$) to final assessment ($M = 108.56$; $SD = 16.23$), but no significant interaction effect ($p > 0.05$) between evaluation and display type (Figure 4).

Figure 3. WMS mean scores (left figure) and RCF mean scores (right figure) for each experimental condition.

Figure 4. TP mean scores for each experimental condition.

These results suggest that the use of VR environments might be a valid alternative for cognitive training in stroke patients. A control sample is, however, missing. Enhanced working memory and attention and concentration abilities may also imply better functional independence in brain injured patients, which is one of the major goals of neuropsychological rehabilitation.

On the other hand, the results revealed no interaction effects between factors ($p > 0.05$), suggesting that these improvements did not interact with display method of exposure. This outcome may indicate that training cognitive functions in VR settings is, probably, an option to traditional training procedures, and that non-expensive displays, like PC screens, are an alternative to more expensive setups such as the HMD.

DISCUSSION

VR applications have long been applied for rehabilitation purposes. Their use to train cognitive functions is now common. VR applications have several advantages when compared to their traditional counterparts. They are immersive, enable a certain amount of free will and they are ecological sound. One entity that has been working as a propeller for their use is the videogame industry. There are now off-the-shelf graphic engines available that are relatively easy to use and that produce realistic and interactive synthetic worlds. Also, on the hardware side, advances in computer components like CPUs and graphic boards are giving a hand, as they are the associated with output devices such as screens, HMD (head mounted devices), or CAVEs (Cave Automatic Virtual Environments).

Screens and HMDs are usually the therapists' choice (CAVE are expensive and require extra manpower). HMDs are immersive and, more often than not, are coupled with a head tracker that emulates one's head movement in the virtual world. On account of all this, they should be "today's special". However, they are not. They are more expensive than screens, they can cause visual discomfort and, above all, as a stand-alone extra they are difficult to justify for lay users such as patients and therapists. Furthermore, the evolution of screen-based displays has placed screens competing shoulder to shoulder with HMD technology. The quality of both general-purpose TVs and computer displays, allied to first-rate and rather cheap sound systems, enable a decent immersive experience that could only be obtained a few years ago by HMD.

This apparent parity is, however, in need of assessment. Accordingly, this study aimed at comparing two samples of stroke patients that had trained memory and attention functions with either an HMD or a PC-screen display. The results suggested that the observed improvement in those functions was independent from the display type used, which supports the idea that screen-based displays may be a sound alternative to HMDs. However, larger sample sizes and/or a greater number of studies are needed to boost power and be more conclusive.

This is important because in western countries, where the elderly population is increasing and the average age of stroke is decreasing, combined with reduced hospitalization periods, the need for rehab applications that can be handled outside health institutions facilities is paramount. Without the direct support of well-trained caregivers, exercises should be devised to be as straightforward as possible. As too should the equipment employed for the VR experience. Under the same circumstances, i.e., producing equivalent therapeutic outcomes, the choice should go towards cheaper and easier-to-handle devices such as screens.

In addition, this study also generally supports the use of VR exercises aimed at training memory and attention functions in stroke patients. The cognitive rehabilitation exercises used in our program were developed according to a cognitive retraining rationale with a focus on

memory and attention functions (3), and support the focus of that rationale on the repetitive training of specific cognitive skills that can help to recover disrupted functions, leading to better adjustment in personal and social domains.

Indeed, irrespective of the specific aim of the each intervention program, meaningful improvement in patient's everyday living activities must be the major goal of rehabilitation. One suggestion for further studies is that evaluation should focus also on the level of activity and engagement in activities of everyday living (ADLs). For example, level of performance in ADLs could be assessed through the caregivers' opinions that could allow the understanding of personal, professional and social adjustment of patients in basic and instrumental ADLs. Also, controlled trials are needed to compare VR-based interventions with other conventional approaches or even with a waiting-list group.

To conclude, despite the need for further empirical support, VR-based applications offer promising prospects in cognitive rehabilitation. Moreover, evidence from motor aspects of using VR environments, which have been well studied (11-13), suggests that the 3D spatial correspondence between movements in the real world and movements in the virtual worlds can benefit training purposes with VR applications. Another important issue with rehabilitation is the patient's motivation to perform the predetermined exercises. Training in a VR setup is typically perceived more as a game and less as a task, and is therefore more engaging and more stimulating than the conventional methods of rehabilitation.

ABSTRACT

Upper body motion impairment is a common after-effect of a stroke. We are developing a novel multisensory therapy system that makes use of augmented feedback and is expected to enhance rehabilitation outcomes. The first phase of the project involved developing algorithms to automatically differentiate between normal and impaired upper body motions. Seven healthy subjects performed two types of scripted actions: (a) elbow flexion and extension and (b) reaching over via elbow flexion and shoulder flexion and adduction. Each action was repeated 10 times as each participant felt most comfortable and also 10 times simulating a common post-stroke impaired motion according to the literature and in consultation with a physiotherapist. Principal component analysis was applied to the upper body trajectories during each action, as observed with a Kinect sensor, to extract the dominant modes of motion. Three classification algorithms and up to three motion modes were examined in order to distinguish between normal and impaired motions. A statistical analysis of the Kinect skeletal tracking data vs. manual annotation confirmed a significant bias in the tracking of an elevated shoulder joint. Despite this bias, leave-one-subject-out cross validation experiments confirmed the effectiveness of the proposed methods in detecting impaired motions (accuracy >95%), even when the impairment involved elevating a shoulder. A

single most dominant motion mode provided sufficient information for the binary classification task. The high accuracy rates validate the use of vision-based pose tracking technologies in identifying motion deficiencies.

INTRODUCTION

Hemiparesis, or weakness on one side of the body, is a common after-effect of a stroke. A well-known body illusion, known as the mirror box illusion, is used in rehabilitation training exercises and has been shown to be effective in restoring mobility (1). During the treatment, the patient enters both arms into a box with a mirror in the middle so that the view of the affected arm is replaced by the mirror reflection of the healthy arm. Simultaneous motion, or attempted motion, of both arms results in artificial visual feedback indicating that it is, in fact, the affected arm that is moving, thus promoting neurorehabilitation.

A closely related body illusion, the rubber hand illusion (2), offers promising potential in strengthening the visual feedback from the mirror box. In this illusion, a plastic arm is placed within view on a table next to the real arm, which is hidden by a screen, and both the rubber hand and the real hand are simultaneously touched by a brush for a few minutes using a rhythmic motion. The temporal synchrony of the seen movements on the rubber hand and the felt movements on the real hand causes the observer to embody the rubber hand so the perceived physical location of the real hand can be shifted towards the seen location of the rubber hand.

Objectives

The main objective of this work is to reproduce and combine the aforementioned illusions in a virtual environment. It is expected that augmenting mirror box therapy with the rubber hand illusion will strengthen the sense of ownership over the artificial visual feedback and will thus enhance the rehabilitative potential. The virtual environment will also enable a wider range of motion than a physical mirror box in which motion is quite constrained.

The project takes advantage of state-of-the-art computer vision and markerless skeleton tracking systems to tackle the engineering challenges and to counter some of the weaknesses identified among many of the virtual rehabilitation technologies (3), e.g., in the user interface or in the interaction methods with the virtual world. The final system is being targeted at an affordable price ($\leq \$200$) to enable wide deployment and home usage. The system is also aimed at being easily configurable so it can be adapted to target a range of mobility impairments.

The skeleton tracking information is processed to identify impaired modes of motions by pre-processing short segments of scripted actions. This information will then be used to modify the profile of subsequent motions in real-time in order to exaggerate impaired motions, for instance by amplifying a reduced range of motion, or exaggerating impaired synergies. Finally, the modified motion is displayed in a virtual environment in real-time and in synchronization with tactile feedback.

Contributions

This paper presents results from the first phase of the project, which focuses on the development of posture categorization pre-processing algorithms and preliminary validation experiments on healthy subjects. Since measuring range of motion deficits is relatively easy via skeleton tracking, the experiments presented here focus on the more challenging task of identifying motion synergies. Impaired motion synergies are a common after-effect of a stroke and refer to the undesirable couplings of human degrees of freedom.

We have also performed preliminary experiments to validate the skeleton tracking algorithm in a specific scenario related to this research. The results identify an inherent bias in tracking the shoulder joint. We provide a short discussion on the consequences of such limitations and how they might affect the assessment of posture and motion.

METHODS

The system employs a consumer depth sensor (a Microsoft Kinect) to capture live video and depth images and to track major skeletal joints of the body in real-time. The PrimeSense™ open source OpenNI and NITE libraries were used to interface with the device. In the final system, touch feedback will be provided via a wearable glove equipped with small vibrating motors, and synchronized with the visual display through a digital I/O board and a digital solid state relay board. The touch feedback interface was not utilised during the experiments reported here as it did not relate to identifying impaired motions.

Experimental Dataset

Two of the most common upper limb flexion synergies present in post-stroke patients were selected according to the Chedoke-McMaster Stroke Assessment 2005 and were simulated by healthy adults. The selected actions were (a) reaching over to the opposite shoulder via elbow flexion and shoulder flexion and adduction (see Figure 1) and (b) elbow flexion (see Figure 2). The stereotypical post-stroke movement synergy associated with flexing the elbow is hiking the shoulder, while reaching across the body is typically accompanied by rotating the trunk (4).

Seven healthy adults (4 males, 3 females) were recruited and asked to use their right arm to perform each of the two actions 20 times in front of the sensor, 10 times normally as they felt most comfortable and 10 times simulating the impaired motion. The 3D coordinates of the upper body skeletal positions were normalized into a subject-centred canonical coordinate frame independent of the body size and the viewing angle (5). The 3D displacement of all upper body skeletal joints in consecutive frames was computed.

Figure 1. Sample color and, depth images in six representative frames over two sequences of reaching across. The top row illustrate a “normal” movement pattern while the bottom row illustrate a simulated “impaired” motion synergy of rotating the trunk when reaching across, common among the post-stroke population.

Figure 2. Sample color, depth, and skeleton tracking images in six representative frames over two sequences of elbow flexion. The top three rows illustrate a “normal” movement pattern while the bottom three rows illustrate a simulated “impaired” motion synergy of hinging the shoulder when flexing the elbow, common among the post-stroke population.

Considerations of Tracking Accuracy

As the real-time skeleton tracking system used in the experiments, i.e., the Kinect (6), is a relatively new technology (introduced in late 2010), its accuracy levels and limitations are not fully known and the existing literature on the topic is sparse. Most notably, Dutta (7) evaluated the depth sensing accuracy of the device and, more recently, Clark et al. (8) validated its skeleton tracking capabilities. When compared to a marker-based Vicon motion capture system as the ground truth, these studies concluded that the Kinect provided sub-centimetre accuracy in depth sensing in a sizable workspace (covering a range from 1 to 3 m from the sensor and a field of view of 54°) and its 3D skeleton tracking had comparable inter-trial reliability. However, Clark et al. also observed tracking biases in estimating the position of the torso and the pelvis.

During our experimentations, it was observed that the skeleton tracking library sometimes estimated joint positions that visually appeared as being systematically biased in certain ways. These biases were mostly observed in the tracking of the elevated shoulder joint and were different from the earlier published results reporting biases in the pelvis and the torso. Therefore, a series of measurements were made to confirm and quantify this visual observation. With the growing interest in applying the Kinect and similar commercially available systems (*e.g.*, ASUS WAMI Xtion) in gait and upper extremity mobility function assessment and other applications in rehabilitation, monitoring, and assistive technologies, it is hoped that the results from these experiments will contribute to obtaining a better understanding of the capabilities and limitations of these technologies.

Automatic Categorization of Motion Impairments

The system is expected to observe a human subject performing a short scripted motion, such as flexing their elbow, and to automatically analyze the motion characteristics of the upper body and detect possible impaired motions.

Principal component analysis (PCA) of the displacement vectors was used to compute the dominant modes of motion over the course of each action and the top N PCA dimensions, along with their corresponding singular values, were used as the feature set in a binary classification to distinguish between normal and simulated impaired motions. Seven-fold leave-one-subject-out cross validation was used to train and validate three binary classification algorithms, each separately trained for identifying impaired motions while

flexing the elbow or while reaching across. The classification algorithms included logistic regression (LR) (9), binary support vector machines (SVM) with radial basis function kernels (10), and Random Forests (RF) (11). The SVM and the RF are state-of-the-art machine learning algorithms (12) while the LR is a simple linear classifier used here as a baseline.

Assessing the Skeleton Tracking in Impaired Motions

With an elevated shoulder, it was visually observed that the 3D skeleton tracking repeatedly underestimated the degree by which the shoulder was elevated by a large margin (see Figure 2). To confirm this observation, in seven videos simulating a motion with a hiked shoulder (one of each subject), ten frames were randomly selected for manual annotation. Two human annotators were separately asked to each mark the location of the left and the right shoulder of the subject at each frame via a mouse click and the elevation angle of the connecting lines, i.e., the angle with the horizontal axis in the 2D image plane, was computed.

For comparison, the same angle with the horizontal axis was also computed based on the 3D tracking data. To calculate the angle, the 3D line segment connecting the estimated location of the left and right shoulder joints, tracked in the depth sensor coordinate frame, was first transformed into the color camera coordinates via the default color-depth registration of the Kinect, i.e., a rigid 3D transformation. The 3D line was then projected onto the image plane based on the default extrinsic and intrinsic calibration parameters of color camera.

Ideally (i.e., in the absence of any inaccuracies or biases in the tracking of the shoulder joints) angles computed from the skeleton tracking data would be very close to those from the manual annotations. If the error in 3D tracking is larger than that of the 2D annotations, it is still expected that the angles be without a bias. That is, while the variance of the angles computed from the 3D tracking could be larger, their mean will ideally be the same as that of the manual annotations.

Admittedly, identifying the shoulder joints visually and via user mouse clicks is not always very accurate. Nevertheless, it is reasonable to assume that the human annotators will mark the left and the right shoulder similarly and their annotations will lead to an unbiased estimate of the elevation angle over the 70 frames. Furthermore, the agreement between the two manual annotators was used as a baseline to confirm the validity of the annotations. Various statistical comparisons between the angles from human annotations and the 3D tracking were used to assess the bias in the 3D tracking of elevated shoulder joints.

FINDINGS

The SVM correctly identified simulated impaired motions with high accuracy (~ 96% and 97%), see Table 1. The RF also provided good, albeit slightly less consistent results (98% and 90%). A single motion mode (i.e., N=1, the most dominant motion over the course of an action) provided sufficient information to discriminate between normal and impaired motions.

Table 1. Classification accuracy in distinguishing between normal vs. simulated impaired motion. The algorithm with the best performance in each action category is boldfaced

Action	N	Classifier		
		Logistic Regression	Support Vector Machine	Random Forest
Reaching	1	54.3	97.1	97.9
Across	3	61.4	85.7	97.1
Elbow	1	64.3	95.7	90.0
Flexion	3	59.3	85.0	92.9

The high rates of accuracy validate the use of commercially available and affordable vision-based pose tracking technologies in identifying motion deficiencies. This encourages further work into the development of the fully integrated tactile and visual virtual reality system for inducing sensory conflicts and targeted rehabilitation therapy. Future work includes validation experiments with real (i.e., not simulated) impaired motions through testing with actual stroke survivors, real-time exaggeration or attenuation of undesirable synergies, and human subject rehabilitation efficacy trials.

Verifying a Tracking Bias

The correlation coefficient (ρ) between the sequence of 70 numbers further illustrates the agreement between the two human annotators ($\rho_{h1-h2} = 0.98$) and the disagreement between the human annotators and the 3D data ($\rho_{3D-h1} = 0.20$ and $\rho_{3D-h2} = 0.15$). The smaller coefficients indicate that the angles computed from the 3D skeletal joints not only underestimated the shoulder elevation angle, but also were less correlated with the true elevation angle.

Finally, the Student's t-test and its non-parametric equivalent, the Wilcoxon signed rank (WSR) test, also rejected the hypothesis that the 70 angles computed from the 3D joints were taken from distributions with the same mean (or median in the case of the non-parametric test) as that of the 2D angles, while strongly confirming that the sequence of the two human annotators indeed were from the same distribution.

The NITE skeleton tracking library provides a 3-value {0, 0.5, and 1} confidence level for each estimated joint position, where 1 is the highest confidence and 0 is the lowest. The confidence values of the estimated position of both shoulder joints, provided by the skeleton tracking library, were at the maximum level (i.e., 1) in all 70 frames. In other words, any discrepancy between the 3D tracking data and the 2D annotations could not be attributed to low confidence tracking.

The results in assessing the tracking of an elevated shoulder highlight the need for a better understanding of the algorithms applied in the skeleton tracking libraries and their underlying assumptions if their usage is to become more widespread in gait and posture assessment. It is interesting, however, to note that despite the inability of the system to track an elevated shoulder joint properly, the developed posture categorization system worked well with a high accuracy of 95.7%. This was only slightly lower (1.4 percentage points when using SVM) than the accuracy rates obtained in identifying trunk rotation. Perhaps even the

slight elevation detected in the placement of the shoulder, combined with other cues from the orientation of the shoulder-elbow and other segments, was sufficient in detecting this compensation mode. It is, however, reasonable to assume that better skeleton tracking would improve the overall identification of compensations.

DISCUSSION

When observing short scripted motions, the most dominant mode of motion, as identified by PCA, provided sufficient information to discriminate between normal and simulated impaired motions with high accuracy. Inherent biases were observed in the tracking of an elevated shoulder via the Kinect sensor. The automatic detection of an impaired motion involving an elevated shoulder was only marginally affected by this bias. However, further research in identifying and quantifying such biases is required so that they can be taken into account when designing rehabilitation and health monitoring systems that use the Kinect.

Current work in completing the first phase of the research focuses on experiments with post-stroke survivors with actual motion impairments to validate the results obtained in classifying the simulated impaired motions evaluated here. Future work towards the full implementation of the sensory-conflict rehabilitation system involves the real-time augmentation of impaired motions, duplicating the rubber hand illusion in a virtual environment via real-time tracking and simultaneous touch feedback, combining the rubber hand illusion with the mirror box illusion via real-time motion augmentation, and clinical trials.

ABSTRACT

This chapter presents a study that evaluates patient engagement and clinical feasibility of an Augmented Reflection Technology system for use in physical rehabilitation of the upper limb following stroke. In particular, TheraMem, an extension of the Augmented Reflection Technology, was assessed on its potential to engage patients in meaningful therapeutic exercise. Six patients participated in a total of 24 sessions of upper limb training with the system. Tailored support for patients performing the exercises was provided based on the severity and level of their impairment. Various configurations of the system were evaluated and adjusted to best match the patient's preferences as well as the therapeutic requirements. It was found that all patients were able to successfully participate and complete the TheraMem intervention at a high level of engagement and motivation over the course of the therapy sessions.

INTRODUCTION

The use of virtual reality and other forms of computer mediated visual feedback can be beneficial for patients in the therapy of motor impairments after stroke, for the improvements of arm function as well as in activities of daily living (1).

* Correspondence: Simon Hoermann, PhD, Department of Information Science, University of Otago, 60 Clyde Street, Dunedin, New Zealand. E-mail: shoermann@infoscience.otago.ac.nz.

Our research group has used computer mediated visual feedback, in the form of Augmented Reflection Technology (ART), to fool users about the properties and capabilities of their hands. Users place their hands in two black boxes where webcams video-capture the hands and transmit the video-streams to a PC. These video-streams are then manipulated and displayed on a screen on top of the boxes (2). Figure 1 illustrates our therapeutic setting of the ART system.

Augmented Reflection Technology allows various ways to visually manipulate what the users see. The fooling of healthy participants into believing that their right hand, displayed on the left side of the screen, is their left hand was extensively evaluated (2,3). In addition the augmentation with virtual backgrounds or 3D models using the ART system is also possible and was previously evaluated (4). Yet another manipulation possibility is the spatial manipulation of the displayed hand by the therapist or operator, which allows change in the position of the user's hand vertically or horizontally in addition to the user's own movement (4).

The TheraMem extension of the ART system, can be described as an augmented reality memory-game incorporating some of the visual manipulation aspects previously described (5). Users move their hand on the floor of the black boxes but experience the video-output on the screen as a three-dimensional environment. In this virtual environment, 12 tiles on each side of the screen are shown.

The task of the users is to try to find matching pairs of plants for the left and the right side by turning exactly one tile for each side. Virtual tiles are turned and the plants are revealed when the user points with a finger or the hand at a tile for a certain amount of time (see Figure 2). The movement of the hand, and the direction that the hand is pointing to, is tracked using a finger-tracking extension specifically added to ART. In addition, TheraMem contains a feature that allows the therapist or operator to amplify the movement of the hand by displaying larger movements on the screen than the user actually performed. The details of this manipulation, the technological background of TheraMem, as well as a detailed study with healthy participants have been previously described (5).

Figure 1. A sketch of the ART system used.

Figure 2. Gameplay of TheraMem for a patient with an impaired right hand.

In this study we use the TheraMem system with patients with stroke to evaluate two capabilities of ART: (a) the augmentation of the visualization of the user's hand within a virtual environment, and (b) manipulation of the displayed hand movement on the screen. The aim is to clinically evaluate the feasibility of using TheraMem for people with chronic (>6 months) stroke in a physiotherapeutic setting.

METHODS

The feasibility of the system for clinical use was evaluated with six patients suffering from motor impairments after a stroke. The evaluation was carried out under the guidance of a physiotherapist with the help of a technical operator who controlled the system and configured the software setting for the individual patients (see Figure 3). This study was preceded by a preliminary study with two subject-matter experts, in which the protocol was tested and fine-tuned. The two experts, of whom one was a trained physiotherapist and the other a postgrad-student with expertise in human-computer interaction, acted as patients but were actively engaged in providing feedback during the session.

System and Clinical Setting

The ART system was placed in a local Physiotherapy Clinic. A secluded room was dedicated for the entire period of the study. The system was placed in a way to allow a quick change between the settings for left and right side impaired people. This was necessary because the physiotherapist was required to sit at the side of the participant's impairment to provide support if required and to get a better picture of how the participant was performing during the exercises.

The operator sat on the left side behind the physiotherapist and the participant. This allowed the operator a good overview and facilitated communication between himself and the

physiotherapist without involving the participant too much. Figure 3 shows a picture of the setting for a participant with a right handed impairment.

Figure 3. ART's setup for clinical use: (a) Operator screen, (b) Black ART Boxes for hands, (c) User, (d) Physiotherapist.

PARTICIPANTS

Six patients with different types of stroke and varying levels of impairment severity of their upper limbs were recruited from the local stroke club. All patients were > 5 years since the onset of stroke. A detailed description of each participant is provided in Table 1. All participants gave written informed consent. The study was approved by the Regional Health and Disability Ethics Committee (Otago, New Zealand).

In the initial assessment, three patients scored a total of 0 in both the Fugl-Meyer measure (wrist & hand) (6) and the Motor Assessment Scale (upper arm, hand, and advanced hand) (7). The other three patients had moderate ratings in Fugl-Meyer and high ratings in the Motor Assessment Scale.

PROCEDURE AND EXPERIMENTAL DESIGN

Each intervention session lasted for about 60 minutes and included a range of hand exercises using ART. These exercises were chosen by the physiotherapist according to the patient's capabilities and could include: pointing at virtual objects, symmetric movements with mirrored visualization of the hands, following predefined virtual shapes with their impaired hand, or interacting with augmented real objects in the virtual environment. The main part of the exercises however, consisted of the use of TheraMem.

Table 1. Participants' characteristics at admission

Code	Age	Gender	Time since stroke	Cause for stroke and diagnosis	Employment status	Upper limb status
PT0	43 y	F	42 y	Infantile left hemiplegia of unknown cause	Independent, Employed	Moderately impaired, uses affected limb for stabilising
PT1	65 y	M	5.5 y	Right hemiplegia due to CVA	Requires moderate assistance, Retired	Severely impaired. Severe spasticity and deformities involving elbow wrist and hand
PT2	63 y	M	6 y	Left hemiplegia due to CVA	Requires moderate assistance, Retired	Severely impaired. Minimal movements available at the shoulder
PT3	47 y	M	45 y	Right hemiplegia of unknown cause	Independent. Employed	Moderately impaired. Active movement available at all the joints of UE
PT4	53 y	M	15 y	Right hemiplegia due to CVA	Independent. Employed	Moderately impaired. Active movement available at all the joints of UE
PT5	49 Y	M	9 y	Right hemiplegia due to CVA	Independent, stays at home	Moderately impaired. Active movement at shoulder and elbow. Poor control of wrist and fingers

For the TheraMem exercise with patient PT5, in addition to the plant models that the user had to match on both sides, an additional set of 22 virtual models of food were integrated in the system. This was to improve the variety of the exercise between sessions and to respond to the feedback of previous users who expressed their preference for additional virtual models. For each of the four sessions, patient PT5 therefore used TheraMem with a different set of 12 models “under” the tiles that he had to match.

For patients with severe spasticity a brief session of warm-up exercises including manual stretching, ‘weight bearing’ exercises and gentle manual vibration at the shoulder were applied to reduce tightness of the limb.

Each participant was clinically assessed during the first session using the following outcome measures: Fugl-Meyer measure for wrist and hand (6); Motor Assessment Scale (MAS), arm, hand and advanced hand sections (7); Muscle tone assessment with the Modified Ashworth scale (8); and Nine Hole Peg test (9). In addition, an assessment of light touch, pain and proprioception sensation in the affected upper limb was undertaken. The same tests were repeated after the fourth session to evaluate the outcome of the intervention. Tests and treatment were administered by the same physiotherapist.

Patients were also interviewed after each trial with TheraMem about their experience with the exercise and equipment. We explored their motivation and engagement with the technology and what they consider important to change and improve the system settings.

After the last session, patients were interviewed about their general experience with the system as well as asked to suggest possible improvements and applications.

NONCLINICAL MEASURES

The physiotherapist rated the patients’ engagement and performance: the ability to understand the instructions, the execution of movements, the participation in activity, the effort, attitude and the acknowledgement of benefits from the patients on a 6 point scale (with 1 being the lowest).

The operator observed and noted technical details, commented on technical problems and asked patients about their experience during the exposure, for example the perceived difficulties and enjoyment experienced.

RESULTS AND DISCUSSION

A total of 128 exercises were administered of which 56 were exercises with TheraMem. All patients were able to play TheraMem and complete the game at least once, in less than three minutes.

Figure 4. Time (a) and Tries (b) required by patients for completion (Mean +/- Std-error).

The average completion-time (Figure 4a) was 195 seconds (range: 116 to 320 seconds); the two less impaired patients (PT0 and PT4) were able to complete the game faster with an average of 147 seconds (see Figure 4). In an earlier study with healthy participants as published in Regenbrecht, Hoermann et al. (4), an average of 136 was measured; our patients in general were slightly slower. The amount of tries (Figure 4b) that participants required to complete the game was, on average, 57.7 tries (range: 43 to 87), which was similar to the average of 54 tries achieved by healthy participants in the earlier study.

Based on the therapist's ratings on patients' overall engagement, the average was above 5 on a 6 point scale. Accordingly, five of the six patients with an engagement rating of above 5, always found it easy to understand the exercise, demonstrated a very positive attitude towards the exercise, and actively participated in the exercises at their maximal effort, whereas one patient did so only for "most of the time" which was deduced from his engagement rating of only 3.5.

Three support systems were introduced to assist patients with more severe motor impairments in performing the exercise. First was the use of the TheraMem built-in movement amplification, where the performed movement of the participant was amplified so that small movements appeared larger in the game. Second, an elbow-splint was used; it was put on the participants' arm after an initial stretching session and this helped the participant to keep the arm in a relatively straight position. Third, a pointing-device was applied – a wooden stick (tongue depressor), was given to the participants to hold with their impaired hand to facilitate pointing (see Figure 5). This was necessary because three participants were not able to keep their affected hand flat on the floor of the box due to muscle contractures/spasticity and were therefore not able to point with their fingers at a specific tile, but instead had to use their entire hand to select the tile.

Figure 5. The use of a pointing-device to support the selection of tiles.

Improvements in the clinical outcome measures after the last session were found for three patients. These were the patients with already moderate ratings in the first assessment. One patient (PT0) improved in the Fugl-Meyer measure (hand) from 4 to 9 (/14), in the Motor Assessment Scale (upper arm) from 5 to 6 (/6) and in the Motor Assessment Scale (hand) from 3 to 4 (/6). Patient PT4 improved in the Fugl-Meyer measure (wrist) from 7 to 8 (/10) whereas patient PT5 improved in the Fugl-Meyer measure (hand) from 5 to 6 (/14).

In the final interview all participants expressed the opinion that the ART system has therapeutic potential for the rehabilitation of motor impairments after stroke. They suggested exercises with the ART system be incorporated in the standard set of therapeutic activities that people with stroke are asked to perform during their rehabilitation phase. In addition, participants expressed their interest in continuing this intervention after the last session. This is especially interesting as two of the participants had not undergone physiotherapy for more than a decade.

Patients suggested that the difficulty and variety of the game should be modifiable. The two patients with less motor impairment especially asked for a more challenging gameplay. The current setting with 12 tiles, even though the content was randomized after each trial, was perceived to be decreasingly less challenging for them after they had played the game a couple of times. In addition, these patients asked for more variety of games and suggested the use of more and different sets of 3D models “under” the tiles. This feedback was incorporated in the study with patient PT5 who was evaluated as the last patient and was very well received by him. The enjoyment rating after each exercise with TheraMem for PT5 stayed uniformly high over the four sessions.

All participants felt comfortable and safe in using the system in the clinical environment. In the final interview three patients stated that they could imagine using the system autonomously without the permanent presence of a physiotherapist and one participant even suggested the use of the system at home. The acquisition of an ART system for the local stroke clubs was also suggested.

CONCLUSION

The results of this study showed that the ART system and specifically its TheraMem extension are feasible for use in the rehabilitation of upper limb movement following stroke. Patients were overall, highly engaged and motivated. The addition of extra 3D models to extend TheraMem gameplay variety was a suggestion raised during the sessions with the first five patients. This suggestion was then implemented and successfully evaluated with the sixth patient.

The relatively small improvements for the individual participants in the clinical outcome measures were expected and can be explained by two reasons. Firstly, undergoing only four sessions of intervention might not allow enough time for a significant change. Secondly, all participants were in the chronic phase after stroke and therefore the chances and amount of improvement was limited.

In order to evaluate the clinical outcomes, a larger-scale controlled trial with more sessions and a longer intervention period is recommended. In such a trial we would expect larger improvements especially for people who have had a stroke more recently.

ACKNOWLEDGMENTS

The authors thank the six participants for their effort and time to take part in this study. Thanks to Dr Marina Moss and Bronwyn Horner for their contribution in the administrative

part of this clinical research. This chapter is based upon a special issue paper published in the International Journal on Disability and Human Development 2014; 13(3) with permission from the publisher De Gruyter in Berlin.

³University of Pittsburgh, Pittsburgh, Pennsylvania, US

ABSTRACT

We introduce a novel rehabilitation technology for upper limb rehabilitation after stroke that combines a virtual reality training paradigm with a myoelectric robotic limb orthosis. Our rehabilitation system is based on clinical guidelines and is designed to recruit specific motor networks to promote neuronal reorganization. The main hypothesis is that the restoration of active movement facilitates the full engagement of motor control networks during motor training. By using a robotic limb orthosis, we are able to restore active arm movement in severely affected stroke patients. In a pilot evaluation, we have successfully deployed and assessed our system with three chronic stroke patients by means of behavioral data and self-report questionnaires. The results show that our system is able to restore up to 60% of the active movement capability of patients. Further, we show that we can assess the specific contribution of the biceps/triceps movement of the paretic arm in a virtual reality bilateral training task. Questionnaire data show enjoyment and acceptance of the developed rehabilitation system and its VR training task.

INTRODUCTION

Currently, stroke is one of the main causes of adult disability, and by 2030 it is expected to be one of the main contributors to the burden of disease worldwide (1). An important goal in the management of stroke patients, and in particular in patients with spasticity, involves restoration of normal limb position and ease of passive and active movement execution with the aim of improving functional outcomes such as the ability to carry out activities of daily living (2). This is a very demanding task for trained therapists and especially problematic in patients with low level of motor control and yet aggravated in the presence of spasticity. In fact, 85% of stroke survivors will present a motor deficit contralateral to the location of the brain lesion (3). Additionally, 20-40% will also suffer of increased muscle tone or spasticity, what will further limit their level of independence in the activities of daily living (4,5). The large economical and psychological impacts of stroke on our society, in particular on relatives and public health systems, make it necessary to find alternative and novel approaches to address these issues.

Nowadays, it is well understood that recovery after stroke depends on brain mechanisms that allow undamaged brain areas, such as contralateral or secondary networks, to take over the functions of the damaged areas (6-8). In the chronic stage of stroke, neuronal plasticity is the main contributor to true recovery, being dependent on the size, severity, and location of the lesion (9,10). Therefore, modern rehabilitation approaches should aim at providing an effective way of driving cortical plasticity and recruiting alternative motor areas to achieve functional brain reorganization, while being accessible to the widest range of patients, in particular to those with the poorest prognostic. During the intent to perform a motor action, cortical areas devoted to motor control generate particular activity patterns – reflecting the synchronization and desynchronization of neural activity – known as Sensory Motor Rhythms (11). These activity patterns encode motor control signals that can reach the paretic arm as long as there are remaining cortico-spinal tracts after stroke (12). Control commands effectively transmitted to the limbs can be assessed by measuring electric potentials at the muscles (electromyogram or EMG). Depending on the brain lesion, the amount of motor control and therefore of active movement is compromised.

To overcome this limitation, we propose a hybrid Virtual Reality (VR) and robotic approach for the restoration of correct limb pose and active movement. The objective of our hybrid system is to restore motor control of the upper limbs when active movement is compromised but weak EMG responses are still present. Our technology is able to detect residual EMG activation and, by means of a robotic orthosis, enable motor impaired patients to exercise movement even when active movement is severely compromised. There are data that suggest that the restoration of active movement may play a crucial role in mobilizing cortical plasticity, and therefore in accelerating recovery after stroke. First, although passive movement exercising is able to engage motor networks by means of proprioceptive feedback (13), it has been shown not to be the most effective way of engaging overt execution motor areas (14). Second, the activation of motor related networks does not only depend on the action intent, but also on the type of actions and their completion. It has been shown that both the observation and performance of meaningful goal oriented actions can engage additional networks such as the Mirror Neuron System (MNS), which is also known as the action recognition system (15-17). The discovery of the MNS has allowed the emergence of novel

stroke rehabilitation approaches based on clear neuroscientific hypotheses on brain recovery mechanisms (18-22). In this project, we propose restoration of active movement as a crucial step to fully engage both the motor control networks and the MNS. Therefore, by restoring active movement and engaging patients in a physical training with meaningful goal oriented actions, our hybrid VR robotic system is designed to facilitate true recovery by means of cortical plasticity.

Previous myoelectric driven robotic interventions (23) have been shown to lead to improved Fugl-Meyer scores of the upper extremities (24) and reduced spasticity as assessed by the modified Ashworth score (25). Many control techniques have been explored for myoelectric driven movement assistance such as fuzzy controllers (26) or compliant systems (27,28). In this project, we use a unique wearable and portable orthosis with integrated myoelectric measurement capabilities that restores correct limb position (mPower1000, Myomo Inc., Boston, USA). Further, we believe the combination of the myoelectric orthosis approach with a VR training paradigm is appropriate because of the inherent properties of VR systems for motor rehabilitation. VR approaches allow for a combination of features including: low cost; personalization of training; unsupervised training; goal-oriented actions; adaptability to a broad range of patients; quantifiable outcome measures; extended feedback; and motivation thanks to the use of game elements (29). Our VR training environment builds on previous work (30,31), on training principles that we have shown to be effective in the chronic phase of stroke (32), and to accelerate recovery in the acute phase of stroke (33). Thus, our hybrid system exploits state-of-the-art information and communication technologies, a myoelectric robotic approach, and a neuroscience based rationale to provide a novel personalized rehabilitation training system that addresses the physical sequels and social impact of stroke. The approach presented here puts special emphasis on patients without (or with minimal) active movement capabilities and those with spasticity, enabling them to train active movement (see figure 1).

Our Study

In our approach, we take advantage of the use VR, because it can support requirements for an effective training. VR allows creating fully controlled environments that define training tasks specifically designed to target the individual needs of patients. Additionally, intensive movement training can be supported through motivating tasks that use augmented feedback and reward (29). VR allows not only for the individualization of training and monitoring by physicians, but also enables patients to play a more active role in their rehabilitation process and self-monitor their own improvements. Besides, our VR based rehabilitation system has been integrated in a game like interaction, capitalizing in motivational factors that are essential for recovery (34). Nevertheless, the main novelty of our approach is the combination of an online adaptation during VR training of the level of assistance provided by a robotic limb orthosis with EMG measurement capability (Figure 1). This technology is designed to restore active movement, compensate for fatigue, and optimize training duration, intensity and repetition.

Figure 6. Diagram of the developed virtual reality and robotic limb orthosis training paradigm showing the role of each technological component (numbered from 1 to 5).

Limb Orthosis

The mPower 1000 robotic device (MyomoInc, Boston, USA) is a portable limb orthosis that is controlled through EMG signals that are measured by an on-board data sampler. Two EMG channels and one actuated joint are used to restore active movement based on biceps/triceps EMG activation or relaxation (see figure 1, points 2–3). The mPower assists its user in the completion of arm movements by means of an embedded electric motor that is activated on the detection of biceps and/or triceps EMG activity. The EMG signals are compared to the baseline EMG activity level of the user and an assistive force is executed (either arm extension or contraction) when EMG changes (muscle contraction or relaxation) are detected. This approach makes therapy accessible to patients with residual EMG activation or involuntary and permanent EMG activation, correcting limb position and allowing them to train active contraction/relaxation to gain movement control. The mPower connects to the virtual environment via a virtual serial port over Bluetooth, allowing its remote control from within the training environment. This wireless connection provides information on the orthosis settings, arm position, and EMG readings, and it allows remote adjustment of the level of motor assistance during training from 0 to 100%.

Tracking

The tracking technology used in this project is the ARToolKit (ARToolworks, Inc., Seattle, USA). The ARToolKit is an augmented reality software toolkit that enables tracking

the position (x, y, z) and orientation in space of predefined unique markers by using a webcam as input device. In our system, the ARToolKit was used to track two handles (7 cm diameter $\times$ 12 cm high) tagged with unique visual markers. Thus, an overhead webcam is used to track the position and orientation of the markers, providing the virtual environment with precise information about the position and movement trajectories of the user's hands during training. Users of the system are instructed to grasp and move these handles around a table top in order to interact with the virtual environment (see figure 2, right panel).

Figure 7. Prototype of the myoelectric based interactive system for rehabilitation. Left panel: An adaptive training in the form of a game defines the training parameters for a bimanual coordination motor task. The training offers augmented feedback on performance, sustains motivation, and automatically modifies the level of motor assistance offered by the limb orthosis. Right panel: The different components of the system (robotic device, tracking setup, and training game task) while being used by a stroke patient.

Virtual Environment

The virtual environment and training task are based on the Neurorehabilitation Training Toolkit (NTT), which is freely accessible at [http:// neurorehabilitation.m-iti.org/NTT](http://neurorehabilitation.m-iti.org/NTT). The NTT is a virtual training environment developed with the open-source game engine Panda3D (www.panda.org) that was designed following neuroscientific and therapeutic guidelines for stroke rehabilitation, such as relevance of training to ADLs, neuronal mechanisms of recovery, narrative, personalization or individualization, augmented feedback, and engagement (30) for a detailed description of the training rational). In essence, the training task is a game experience consisting of a bimanual coordination task that uses upper limb motor actions as control signals. Bimanual upper limb training was selected because it has been shown to enhance excitability of cortical motor networks and lead to improved functional outcomes (35,36). The bimanual motor actions are mapped onto the actions of an avatar that controls a glider in the virtual environment, i.e., the physical arm movements of

the user are used to control the steering direction of a virtual glider (see figure 2, left panel). Feedback on performance and on-screen information is extensively used to inform the user on the immediate game goals and motor actions to be performed, as well as a reward mechanism. The goal of the game is to gather the largest number possible of collectable items in the virtual environment. Two types of collectable objects are present – easy (balloons) and difficult (stars) – that are accumulated to an on-screen score to provide feedback on performance. In addition, the amount of arm movement measured by the limb orthosis is also provided as a visual score. All tracking and training data are logged as a text file for later analysis.

Pilot Evaluation

The objective of this pilot study was to assess the acceptance and usability of the system, as well as the impact of the level of assistance of the limb orthosis on task performance and overall arm movement. We evaluated the system with 3 chronic stroke survivors (47–63 years old; > 6 months post-stroke) in a laboratory setting at the University of Pittsburgh (see table 1). All subjects had a very low level of control of their paretic arm but were able to generate voluntary EMG activation, and hence able to drive the robotic orthosis. All subjects used the robotic orthosis in biceps mode (only controlled by biceps EMG activity) and used the system for a single training session of approximately 20 minutes. During the training session, the level of assistance of the orthosis was randomly changed between 40% and 90% every time a virtual item was collected. After the training session, subjects were asked to report on their experience by answering a questionnaire about enjoyment, engagement and usability rated using a Likert scale from 1 to 5. All subjects gave their informed consent to participate in this study.

FINDINGS

This is a unique system that not only engages users in a game-like VR training experience, but also makes use of a myoelectric capable orthosis to restore active movement. However, the effectiveness of the orthosis assistance in movement restoration and how to optimally integrate it in an interactive training experience need to be studied before any longitudinal deployment. For these reasons, we performed a number of experiments in which we exposed three stroke survivors to single training sessions of the combined VR and myoelectric limb orthosis paradigm. The integrated system allows us to simultaneously

measure both the movement of the arm end effector (tracked by a marker on the handle) and the specific movement of the biceps as measured by the orthosis (see figure 2, right panel). Training data were recorded synchronously with tracking data as well as the limb orthosis settings.

The analysis of the multimodal data revealed a linear effect of the level of assistance of the limb orthosis with the amount of biceps movement as measured by the system in deg/s (see figure 3, left panel). The existence of this linear relationship between level of assistance and movement execution is an important feature of the system because it will enable us to integrate, into the VR training environment itself, straight forward statistical modeling techniques to automatically adjust the level of assistance depending on the characteristics of each user. This will allow us to improve the level of motor control or compensate for fatigue or loss of force during training. Moreover, the system provides us with additional valuable data, allowing us to quantify the particular contribution of the biceps/triceps movement to overall movement (Figure 3, middle panel). In our experiment we could assess that the movement of the elbow joint (measured by the limb orthosis) showed a low correlation coefficient with that of the end effector (37). This reveals a low contribution of the elbow joint, and therefore a low biceps/triceps contribution, to the bimanual control task defined in our training. This correlation indicates that possible compensatory strategies were used during training. Further, our VR training system allows us assess and compare differences between paretic and non-paretic arms. This enables us to monitor recovery over time using the non-paretic arm as reference. Of particular interest is the comparison of movement capability of the paretic and non-paretic arms when the orthosis assistance is enabled. During our pilot experiment we have quantified the impact of the active orthosis on the overall movement of the arm and we verified that the myoelectric orthosis was able to restore the paretic arm movement to about 60% of the non-paretic arm in patient 3. These results are yet more remarkable when compared to the absence of assistance, in which case the overall movement of the paretic arm was below 30% of that of the non-paretic one (see figure 3, right panel).

Figure 8. Effect of the myoelectric limb orthosis during the virtual training task. Left panel: Effect of the level of assistance of the limb orthosis on the amount of biceps movement. Middle panel: Quantification of the contribution of the biceps movement to the overall arm movement, computed as the correlation value of the biceps and arm movements during training. Right panel: Restoration of arm movement. % of arm movement of the paretic arm as compared to the non-paretic arm in presence and absence of robotic assistance. Data from patient 3.

Questionnaire data revealed a good acceptance of the system, the most positive aspects being: fun [4.3], entertaining [4], and willingness to use it as regular motor training [4.6]. Subjects reported that the system was easy to understand [3.6] but also considered it a challenging training task [1.6].

DISCUSSION

Here we presented a novel hybrid system that integrates a VR training and a myoelectric limb orthosis. This system is an extension of the Neurorehabilitation Training Toolkit (NTT) that aims at restoring arm movement in severely affected stroke patients by integrating an EMG driven portable robotic limb orthosis. This system is specifically designed to be used by patients without or with minimal active movement capabilities, i.e., those with the poorest prognostic, enabling them to train active movement. The robotic orthosis is combined with a gaming training environment that is based on clinical guidelines and designed to recruit the MNS and to promote neuronal reorganization. By using a robotic limb orthosis, we are able to restore active arm movement in severely affected stroke patients. We hypothesize that the restoration of active movement facilitates the full engagement of motor control networks during motor training.

In this first pilot experiment, we have successfully deployed and tested our bio-hybrid VR interactive rehabilitation system with three chronic stroke patients. The system was evaluated by means of quantitative behavioral data – acquired by the system itself – and self-report questionnaires. Initial results show that our system is capable of online adjusting the assistance level provided by the orthosis, and that the level of assistance has a linear effect on the overall arm movement. We showed that the myoelectric orthosis is able to restore up to 60% of the active movement capability. Although encouraging, these results require further investigation to better understand how the level of assistance relates to improvements in motor control and also to the overall recovery process of the paretic arm in a longitudinal intervention. Another of the strengths of the presented approach is that our technology allows assessing the individual contribution of the biceps/triceps movement to the overall bilateral training task. We have shown that we can objectively assess and monitor the active contribution of the elbow joint to overall arm movement as well as detect and quantify the presence of compensatory strategies. Questionnaire data reveal a high level of acceptance of the system and its VR training task, although it was found to be challenging. This is an expectable result because in this experimental protocol patients with no or very low active movement were exposed to varying levels of orthosis assistance, including low levels of assistance. This effect will be minimized in the future by using an algorithmic solution to automatically adjust the level of assistance to each patient, thus maximizing the outcome of training. The long-term impact of these technologies will be assessed in a randomized controlled trial in the inpatient rehabilitation unit (RHB) of the Hospital of Funchal.

ACKNOWLEDGMENTS

The authors would like to thank Prof. Daniel P. Siewiorek (Carnegie Mellon University) and Steve Kelly (Myomo Inc.) for their support and contribution to this project. Support for

this research was provided by the Fundação para a Ciência e Tecnologia (Portuguese Foundation for Science and Technology) through the Carnegie Mellon Portugal Program under grant CMU-Pt/0004/2007, and through the EC FP7 program under grant 303891 RehabNet FP7-PEOPLE-2011-CIG. This chapter is based upon a special issue paper published in the International Journal on Disability and Human Development 2014;13(3) with permission from the publisher De Gruyter in Berlin.

Chapter 76

CHILDHOOD VASCULITIC STROKE

Aleksandra Mineyko and Adam Kirton*

Section of Neurology, Department of Pediatrics,
Alberta Children's Hospital Research Institute, Calgary, Alberta, Canada

ABSTRACT

Arteriopathy is the leading cause of childhood arterial ischemic stroke, but the pathophysiology is poorly understood. Vascular inflammation is a frequently considered, but rarely proven mechanism. This chapter considers the pathophysiology of primary and secondary vasculitides, and their role in pediatric stroke. Pathologically-proven small vessel central nervous system vasculitis is an inflammatory disease model with treatments that improve outcome while primary large vessel arteriopathy, which has many features suggestive of inflammation, and typically lacks definitive histologic proof of vasculitis. Potentially useful biomarkers, advances in neuroimaging, and the pathophysiological approach to childhood vasculitic stroke will be discussed along with unanswered clinical questions and controversies.

OVERVIEW

Stroke is defined as focal cerebral injury secondary to occlusion or rupture of a cerebral blood vessel. Ischemic stroke can occur when the occlusion is present in an artery (arterial ischemic stroke [AIS]) or vein (cerebral sinus venous thrombosis [CSVT]). Hemorrhagic stroke results from a rupture of a cerebral blood vessel. The estimated incidence of childhood AIS is 0.6 to 7.9 per 100,000 while that of hemorrhagic stroke is 0.4 to 13.0 per 100,000 [1]. Childhood stroke causes significant lifelong morbidity, mortality, and economic burden [2-4]. Although prothrombotic, cardiac and hematologic risk factors play a role in pediatric stroke, disorders of the cerebral blood vessels themselves or vasculopathy are the leading mechanism

of both their cause and recurrence [5-7]. An incomplete understanding of pathophysiology of childhood vasculopathy has precluded the development of targeted therapy and prevention strategies. A recent large international study of childhood AIS [5] suggested that inflammatory mechanisms were a leading cause of arteriopathy, implicating vasculitis and the role of anti-inflammatory medication therapy. However, such suggestions are highly controversial and not yet part of expert consensus guidelines for stroke management in children [8, 9]. Childhood primary angiitis of the central nervous system (cPACNS) represents the prototypical syndromes of pediatric vasculitic stroke and is a recognized category of inflammatory brain diseases of childhood [10]; and an important cause of pediatric AIS. Pediatric cerebrovascular disorders and CNS vasculitis are considered elsewhere [11, 12].

VASCULAR PATTERNS OF STROKE

Arterial Involvement

Patterns of stroke are identified by the region of brain supplied by the affected vessel. AIS patterns are mainly classified as large- or small-vessel infarcts (Figure 1).

Figure 1. Vascular stroke patterns. A – C. Large vessel right middle cerebral artery (MCA) territory ischemic stroke. D- E. Small vessel ischemic infarcts. Hypodensity on axial CT (A) in the right MCA territory indicative of acute ischemic changes. Hyperintensity on axial DWI (B) and hypointensity on axial ADC (C), consistent with restricted diffusion in the right MCA territory indicative of an acute arterial ischemic stroke in this territory. Bilateral, punctate hyperintense DWI (D) and hypointense on ADC (E) lesions represent small vessel ischemic infarcts.

Large vessel infarcts typically result in wedge-shaped parenchymal lesions that occur secondary to occlusion of branches of the major arteries of the circle of Willis. Small vessel diseases result in smaller, often multifocal or diffuse parenchymal infarcts with highly variable imaging appearances. The vessel size and distribution of infarct helps determine the etiology of the stroke. Symptoms and signs are dependent on the area of cerebral damage. Large vessel infarcts usually present with sudden onset focal neurological deficits such as contralateral hemiparesis when the middle cerebral artery (MCA) is occluded. In contrast, strokes in small vessel territories more often present with subacute, non-localizing neurological complaints such as headache, behavioral changes, seizures, or cognitive decline [13-15].

Venous Involvement

Cerebral sinus venous thrombosis is identified by thrombus in the cerebral venous system. Unlike arterial strokes, this does not always lead to parenchymal injury. If the increased venous blood pressure exceeds arterial pressure, insufficient blood supply leads to focal ischemia. Secondary hemorrhage often occurs due to venous back pressure in ischemic lesions.

In fact, purely ischemic infarcts were described in only 13% of 160 pediatric CSVT cases compared to hemorrhagic infarcts in 30 - 40% [16, 17]. The clinical features of CSVT can be subtle, non-specific, and diffuse. Patients can present with signs and symptoms of raised intracranial pressure such as protracted headaches, papilledema and diplopia, seizures, or decreased level of consciousness [18].

STROKE CLASSIFICATION

Adult stroke etiologies are often classified according to the TOAST (Trial of Org 10172 in Acute Stroke Treatment) criteria which divided stroke subtypes into large-artery atherosclerotic, cardioembolic, small vessel lacunar, other determined and undetermined etiology [19]. Despite common use in adult stroke care and research, applicability of TOAST criteria appears limited in young stroke patients where many etiologies are classified as other or undetermined [20].

In childhood AIS, where non-atherosclerotic arteriopathy predominates, reliance on TOAST classification is inadequate to further the understanding of disease [5-7]. Thus, a new system with a more comprehensive classification of pediatric stroke etiologies is currently being developed. With a focus on arteriopathy, the Childhood AIS Standardized Classification and Diagnostic Evaluation (CASCADE) attempts to address the unique causes of stroke in children [21].

This is important step forward because it highlights the importance of considering vascular inflammatory mechanisms. CASCADE specifies diagnostic categories that consider the possibility of vasculitis. As elaborated below, categories include small-vessel arteriopathy of childhood, unilateral focal cerebral arteriopathy (FCA) of childhood, transient cerebral

arteriopathy (TCA), bilateral cerebral arteriopathy of childhood, post-varicella angiopathy (PVA), aortic/cervical arteriopathy, cardioembolic, and multifactorial etiologies [21].

NOSOLOGY AND CLASSIFICATION OF VASCULITIS

Vasculitis of the central nervous system is divided into primary and secondary causes. Secondary causes occur in the context of other systemic conditions such as systemic vasculitides. Vasculitis is defined as inflammation of blood vessel walls for at least some time during the course of the disease and can affect arteries and veins of varying caliber. The Revised 2012 Chapel Hill Consensus Conferences (CHCC) [22] provides a useful nosology for the classification of vasculitis according to the caliber of vessels involved, vessel type, and the associated clinical and pathologic features. Large vessel vasculitis, typified by giant cell arteritis (GCA) and Takayasu arteritis (TAK), affects the aorta, its major branches and analogous veins. The prototypical forms of medium vessel vasculitis include polyarteritis nodosa (PAN) and Kawasaki disease (KD), which involves main visceral arteries, veins and initial branches. The category of small vessel vasculitis recognizes involvement of intraparenchymal arteries, arterioles, capillaries, veins and venules, with a disease mechanism related to anti-neutrophil cytoplasmic antibody (ANCA) and circulating immune complexes (IC). The category of ANCA-associated vasculitis (AAV) includes granulomatosis with polyangiitis (GPA), eosinophilic granulomatosis with polyangiitis (EGPA), and microscopic polyangiitis (MPA), while vasculitic disorders associated with circulating IC include IgA vasculitis-associated Henoch-Schönlein purpura (IgAV/HSP), cryoglobulinemic vasculitis (CV), and C1q antibody-associated hypocomplementemia urticarial vasculitis (C1q/HUV). Vasculitis without a predominant vessel size and caliber, respectively from small to large, involving arteries, veins and capillaries, comprises the category of variable vessel vasculitis, characteristic of Behçet disease (BD) and Cogan syndrome (CS). There is a category of vasculitis associated with systemic disorders such as rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), sarcoidosis, and Sjogren syndrome. A category of vasculitis associated with an infectious process is described by a prefix for the presumed etiopathogenic agent. The category of single-organ vasculitis (SOV) is exemplified by adult and childhood PACNS.

Although applicable to pediatric patients, this nosology [22] was not specifically designed for this population. Accordingly, the European League against Rheumatism (EULAR) and the Pediatric Rheumatology European Society (PReS) [23] developed consensus criteria for the classification of childhood vasculitis designated cPAN, cGPA, and cMPA for the childhood forms of the respective adult disorders, with others including, TAK, KD, IgAV/HSP were unabbreviated because of their common pediatric occurrence. Childhood PACNS and primary CNS vasculitis (PCNSV) are equivalent terms for a spectrum of disease subtypes, still incompletely classified and distinguished by vessel size, angiographic and pathological findings, and the presence or absence of long-term progression [24, 25]; they are further divided into large-medium and small-vessel forms. Table 1 summarizes the potential inflammatory and non-inflammatory etiologies of childhood CNS vasculopathy.

Table 1. Etiology of CNS Vasculopathy in Children*

Primary CNS vasculitis	Large-Medium Vessel Progressive Non-progressive FCA TCA PVA Small vessel
Systemic Vasculitis	Large Vessel Vasculitis Takayasu arteritis Medium Vessel Vasculitis Polyarteritis Nodosa Kawasaki Disease Small Vessel Vasculitis ANCA-Associated Vasculitis (GPA, EGPA, MPA) Immune-Complex Vasculitis (CV, IgAV, HUV(C1q) Variable Vessel Vasculitis (BD, CS)
Other Vasculitides	Sjogren syndrome Systemic lupus erythematosus Behçet syndrome
Post- and Para-infectious vasculitis	Bacterial <i>Mycobacterium tuberculosis</i> <i>Mycoplasma pneumonia</i> <i>Streptococcus pneumonia</i> Viral HIV/AIDS Varicella zoster Parvovirus B19 Influenza A Enterovirus Spirochete <i>Borrelia Burgdorferi</i>
Systemic Inflammatory Disease	Inflammatory bowel disease Neurosarcoidosis
Non-Inflammatory Arteriopathy	Moyamoya syndrome Fibromuscular dysplasia Dissection Radiation arteriopathy Hemoglobinopathy (Sickle cell disease) CADASIL Fabry disease Reversible cerebral vasoconstriction syndrome
Drug-Induced Arteriopathy	Cocaine Amphetamines

*Adapted from [23, 42, 43, 51]; and Gowdie P, Twilt M, Benseler SM. Primary and secondary central nervous system vasculitis. *J Child Neurol* 2012; 27: 1448-1459. Abbreviations: FCA, focal cerebral arteriopathy; TCA, transient cerebral arteriopathy; PVA, post-varicella arteriopathy; ANCA, anti-neutrophil cytoplasm antibody; GPA, granulomatosis with polyangiitis; EGPA, eosinophilic granulomatosis with polyangiitis; MPA, microscopic polyangiitis; CV: cryoglobulinemic vasculitis; IgAV, IgA vasculitis; HUV C1q, hypocomplementemia urticarial vasculitis associated with C1q antibodies; BD: Behçet disease; CS, Cogan syndrome; HIV, human immunodeficiency virus; AIDS, acquired immune deficiency virus syndrome; CADASIL, Cerebral autosomal dominant arteriopathy with subcortical Infarcts.

PRIMARY VASCULITIDES

Large Vessel Vasculitis

Systemic large vessel vasculitis leads to inflammatory stenosis of the aorta and its proximal branches. Takayasu arteritis (TAK) is the prototypical childhood disorder diagnosed in the presence of one of the following criteria including, decreased peripheral pulses and/or claudication, blood pressure difference of > 10 mmHg between arms, bruits over the aorta or its branches, or hypertension [23]. Stroke occurrence has been noted in 17% of 230 reported children with TAK between 1994 and 2008 [26]. There is a risk of focal AIS from thromboembolism as well as hypoperfusion-induced brain infarction secondary to proximal arterial stenosis. While the pediatric presentation of TAK includes hypertension similar to adults [27], affected children more commonly manifest fever, weight loss, abdominal pain, and headaches [26].

Medium Vessel Vasculitis

Two classic medium vessel vasculitides PAN and KD may manifest neurological involvement including a small risk of cerebrovascular disease. The diagnosis of cPAN requires evidence of systemic inflammatory disease with evidence of necrotizing vasculitis or angiographic abnormalities of medium- to small-sized arteries plus one of five criteria including, skin involvement, myalgia, hypertension, peripheral neuropathy, and renal involvement [28]. Neurological manifestations are seen in up to 50% of patients but consist mostly of peripheral nervous system involvement [29, 30]. In a survey of patients with PAN, 16% of 110 pediatric patients (but one third of those with systemic PAN) had neurological symptoms. Four of 63 patients with systemic PAN had cerebral aneurysms [31] and cases of intracerebral hemorrhage have also been reported in the literature [32].

The diagnosis of KD requires the presence of fever for at least five days plus four of the following criteria including, desquamation of extremities or perineum, polymorphous exanthema, bilateral conjunctiva injection, injection of oral or pharyngeal mucosa, and cervical lymphadenopathy [23]. The disease affects the coronary arteries and stroke as a complication has only rarely been reported, predominantly large-vessel cardioembolic stroke but also cerebral micro-hemorrhages. [33-35] Evaluation of 24 patients with KD using magnetic resonance imaging (MRI) revealed only one cryptogenic cardioembolic posterior inferior cerebellar artery (PICA) infarct [36]. Risk is potentially higher in patients with ventricular dysfunction secondary to myocardial infarction or arrhythmia. Thus, although a rare occurrence, stroke should be considered in children with signs or histories of medium vessel vasculitis and neurological symptoms, particularly acute focal neurological deficits.

Small Vessel Vasculitis

GPA, classified as an AAV affecting small vessels, is recognized by the presence of two of nasal-oral inflammation, abnormal chest x-ray, urinalysis, and granulomatous

inflammation on tissue biopsy [23]. Neurologically, it is most often associated with contiguous extension of granulomas leading to pachymeningitis while reports of cerebral vasculitis or AIS are rare. Similarly, children with EGPA rarely present with AIS [37]. IgAV/HSP is a common disorder of early childhood characterized by nonthrombocytopenic purpura, arthralgia, nephritis, and abdominal pain [29, 30]. Stroke types associated with IgAV/HSP include hemorrhagic and arterial ischemic strokes as well as sinus venous thrombosis [29, 30]. However, pediatric stroke is rare in IgAV/HSP, described in only 1-8% of patients [29, 38, 39].

Variable Vessel Vasculitis

Behçet syndrome is a rare primary systemic vasculitis of childhood characterized by mucocutaneous ulcers and uveitis. CNS involvement includes idiopathic intracranial hypertension and meningoencephalitis which occur in up to 50% of patients [29]. Cerebrovascular disease has been reported in 30% of adults. Occurrence in children is recognized in isolated case reports but the true incidence is unknown and likely low. Venous sinus thrombosis may be most common but arterial infarcts and aneurysms are also described [40].

CNS Vasculitis

Isolated central nervous system vasculitis in children has been referred to in the literature as cPACNS. Specific subtypes are distinguished based on vessel size, angiographic and pathological findings, and the presence or absence of long-term progression [24, 25]. Large-medium vessel vasculitis is divided into progressive and non-progressive types [24, 25, 41], the latter syndrome being highly comparable to other childhood cerebral arteriopathies such as TCA and FCA. Current classifications remain incomplete and controversial, as discussed here and elsewhere [24, 25, 42] but provides a practical, clinically relevant framework. It should be noted that the following discussion is based on evidence supporting a vasculitic mechanism for large-medium cPACNS but that definitive diagnostic testing does not exist and the acceptance of this mechanism varies widely within the pediatric stroke community.

Large-Medium Vessel Type

Most large/medium vessel primary CNS vasculitis in children is non-progressive and unilateral. As such, it bears marked similarity to other cerebral arteriopathies causing stroke in otherwise healthy children, namely TCA and FCA. It is possible they represent the same disease or closely related diseases within a spectrum [41, 43]. The following features are shared across these syndromes and are used in support of the clinical diagnosis [6, 21, 25, 42]:

- (1) Location: Unilateral arteriopathy of the large vessels of the anterior circulation, typically the distal internal carotid artery (ICA) and proximal segments of the MCA and anterior cerebral artery (ACA).
- (2) Arteriopathy characteristics: Unique angiographic appearance with unilateral focal and segmental stenosis often with contiguous alternating areas of stenosis and dilatation with a “banding” or “striated” appearance. More definitive features of other arteriopathies such as dissection or Moyamoya are absent (see differential diagnosis below).
- (3) Time course: A dynamic nature with early serial vascular imaging often demonstrating a fluctuating course of arterial changes on a scale of days to weeks.
- (4) Resolution: A monophasic illness when followed over the longer term with follow up imaging after 6 months confirming no progression, and variable resolution of arterial changes.

A representative case example of this syndrome is presented in Figure 2. Ironically, the most common syndrome of AIS in school-aged children is also the least understood. Definitive evidence of an inflammatory pathophysiology is lacking in most cases, supporting the consideration of alternative diagnostic terminologies. The diagnosis of TCA requires angiography within 3 months of stroke demonstrating unilateral focal or segmental stenosis or occlusion of the distal internal carotid or proximal MCA and ACA and lack of progression at 6 months [42, 44, 45]. Moreover, FCA shares the same features as TCA [6, 21] but facilitates earlier diagnosis, respecting the inability to exclude progression until 6 months later; PVA discussed below shares many of these features. Therefore, while a legitimate diagnostic entity of its own [41, 43, 46], the non-progressive variety of large-vessel cPACNS shares many features with other childhood cerebral arteriopathies, the spectrum of which should be considered in the evaluation and management of affected children.

Bilateral large vessel arteriopathy without collaterals is a distinct, less common disease classification within CASCADE [21]. Research to date has been limited but suggests large vessel cPACNS may be bilateral in up to 20% of children [41, 47]. Whether this represents a more widespread version of the more typical disease (akin to optic neuritis), a marker of progressive large vessel cPACNS [41, 45], or falls within a spectrum of other bilateral arteriopathies such as fibromuscular dysplasia or Moyamoya disease [45] remains to be determined. Progressive large-medium vessel cPACNS also appears to be uncommon and is more likely to present with long-standing, non-focal, diffuse symptoms such as neurocognitive dysfunction, headaches, and seizures. Imaging may reveal multifocal, bilateral parenchymal lesions on MRI, and multiple, bilateral stenoses of the distal vessels on angiography [24, 41]. Ante mortem tissue diagnosis is not possible due to involvement of larger intracranial arteries. The result is reliance on neuroimaging, specifically angiography, which continues to improve but cannot definitively implicate inflammatory pathophysiology or immediately identify a progressive from non-progressive prognosis. Long-term surveillance and outcome studies are required to better understand the natural history and predictors of recurrent forms of large-medium vessel cPACNS.

Figure 2. Focal cerebral arteriopathy and AIS in a 15-year-old boy with acute right hemiplegia and hemianesthesia. (A) Diffusion MRI on day 1 shows faint restricted diffusion limited to the posterior putamen and internal capsule. (B) MRA shows reduced ICA and MCA flow with irregular narrowing of left MCA (arrow). (C) Repeat diffusion MRI on day 11 shows new restricted diffusion extending throughout the corona radiata and small cortical areas within the MCA and ACA territories (arrows). (D) Conventional angiography (left ICA injection) demonstrates severe irregularity of the distal ICA and proximal MCA with alternating “bands” of narrowing. The ACA is now occluded.

Small Vessel Type

Primary vasculitis of the small cerebral blood vessels is better defined than those described above, involving large vessels. Unlike large vessel disease, definitive evidence of vessel wall inflammation is often obtained by brain biopsy, allowing pathological confirmation of vasculitis [15, 48]. Patients may present with focal symptoms but are more likely to develop subacute, non-localizing neurological complaints such as headache, behavioral changes, seizures, school failure or cognitive decline [13-15]. Strokes, when they occur, do not conform to large vessel territories and ischemic lesions can be highly variable in character and distribution [15, 48]. Hemorrhagic lesions may also occur although the incidence is probably <10% [49]. Neuroimaging is far less specific compared to the large vessel diseases described above. Non-invasive arterial imaging employing computed tomography angiography (CTA) and magnetic resonance angiography (MRA) is typically normal while parenchymal MRI can range from normal to diffusely abnormal with a wide array of lesion characteristics [15]. Conventional angiography is also often negative and small vessel cPACNS may also be referred to as angiography-negative vasculitis [14, 15, 43, 50]. Diagnostic criteria proposed by Calabrese and colleagues [46] for adult PACNS have been

applied to children [41, 51]. These include: (1) an acquired neurologic deficit that remains unexplained after thorough evaluation, (2) either classic angiographic or histopathologic features of angitis within the CNS, and (3) no evidence of systemic vasculitis or any other condition to which the angiographic or pathologic features could be attributed [46]. In the face of less severely symptomatic children when angiography is negative and brain biopsy is deferred, the clinical diagnoses of “probable” small vessel cPACNS may be considered.

SECONDARY VASCULITIDES

Connective Tissue Disorders

Neuropsychiatric manifestations in SLE may occur as a direct consequence of the disease, such as antibody-mediated neuronal dysfunction, or its treatment. Vascular mechanisms may also occur including complement activated vascular inflammation, Libman-Sacks endocarditis, or thrombosis due to hypercoagulable states associated with high titers of lupus anticoagulant and phospholipid antibodies [52]. The risk of AIS, CSVT, and intracranial hemorrhage are all increased in SLE. Patients most commonly present with angiogram-negative small vessel vasculitis or sinus venous thrombosis [52]. Of 185 pediatric patients with SLE reviewed retrospectively, 64 (34.6%) had neuropsychiatric symptoms: 1 (0.5%) had transient ischemic attack (TIA), 18 (9.7%) had ischemic stroke, 4 (2.1%) had venous thrombosis, and 2 (1.1%) had intracranial hemorrhage [53]. Another study found cerebrovascular disease to be present in a total of 24% of their retrospective cohort [52]. Cardioembolic stroke secondary to Libman-Sacks, nonbacterial endocarditis has rarely been reported in children [54]. Sjogren syndrome is an autoimmune disease rarely encountered in children [55]. Case reports of adolescents with Sjogren syndrome and stroke have been reported [56, 57], as did one presenting with Moyamoya syndrome. A study comparing patients of all ages found cerebrovascular disease was less common in Sjogren syndrome compared to SLE despite comparable incidence of neuropsychiatric symptoms [58].

Infection

An association of pediatric stroke with infection has long been suspected [59], and the associated pathophysiology may be explained by direct infection of cerebral arteries or a “triggering” effect leading to inflammatory cerebral arteriopathy that is para- or post-infectious. The most direct evidence is described in children with stroke associated with bacterial meningitis, in which the pathophysiology is presumed to result from inflammation of perforating vessels in the subarachnoid space that traverse infected meninges [60, 61]. Large artery involvement has also been reported in association with bacterial meningitis [60, 61]. A late-onset, large vessel arteriopathy, beginning during the recovery phases of bacterial meningitis is associated with poor outcome [62, 63]. The incidence of this infective arteriopathy may be underestimated, reported in 37% of consecutive adults undergoing conventional angiography after bacterial meningitis [64]. The diagnosis of meningitis-related arteriopathy is relatively easy with clear evidence of bacterial meningitis. However, other

infectious mechanisms may be more occult, the timelines less clear, and their associations with stroke less definitive.

Although the association of large vessel cerebral arteriopathy in children with inflammation is unclear, there are many similarities between large/medium cPACNS PVA. An association was demonstrated between *Varicella zoster virus* (VZV) infection was suggested in case-control [65] and cohort studies [66] of childhood AIS. Focal cerebral arteriopathy associated with recent VZV infection has also been implied by case reports [67-74]. Cerebrospinal fluid (CSF) pleocytosis [72, 73, 75] and VZV antigens [67, 70, 71, 73] have occasionally been demonstrated in patients with stroke and recent VZV infection. Herpes zoster ophthalmicus associated with arteriopathy and stroke has been described in both adults [76-78] and children [79-81]. Tissue analysis from biopsy [82] and postmortem studied patients with PVA [83] revealed vasculitis with lymphocytic infiltration and VZV-positive immunohistochemistry with antigen deposition in the smooth muscle layer of the vessel wall, suggested both direct infiltration and immune-mediated inflammation.

The clinical presentation, neuroimaging, and natural history of PVA are indistinguishable from TCA except for the history of VZV infection within the preceding 12 months [42]. The course is monophasic with subsequent stabilization or improvement of arteriopathy over months [84]. Consistent with proximal MCA involvement, infarct patterns typically involve lenticulostriate territories resulting primarily in deep basal ganglia infarcts [44, 45]. Proximal segments of the ICA and ACA may also be involved as seen in TCA, FCA and cPACNS. Therefore both direct and indirect parainfectious mechanisms may be responsible for some vasculitis-associated strokes in children.

Other infectious agents are less commonly associated with arteriopathic stroke in children (Table 1); and this list is illustrative rather than exhaustive. Fusiform aneurysms, focal arteriopathy, and stroke occur in children with human immunodeficiency virus type 1 (HIV1) [85-87] and vasculitis has been shown on autopsy in children with the acquired immune deficiency syndrome (AIDS) [88]. Isolated reports have associated neuroborreliosis, [89-91] parvovirus B19, [92, 93], influenza A [94], Enterovirus [95], and *Mycoplasma pneumoniae* [96-98] with focal cerebral arteriopathy and stroke in the pediatric population. It is important to note that isolated case reports do not prove causation [25].

Rather than specific infectious pathogens, para- or post-infectious mechanisms in general have been implicated in childhood cerebral arteriopathy pathogenesis and increased stroke risk. Population-based studies have demonstrated associations between recent preceding infections and arterial strokes in children [6]. The association between acute infections and increased risk of vascular events is also recognized in the adult literature [99-101]. The Vascular Effects of Infection in Pediatric Stroke (VIPS) study is an international research endeavor designed to test the hypothesis that infection predisposes children to arteriopathy, AIS, and stroke recurrence [102].

DIAGNOSTIC WORK UP

The diagnostic work up of childhood stroke due to arteriopathy is summarized in Table 2.

Table 2. Diagnostic Algorithm of Childhood Stroke Due to CNS Vasculitis*

History	Neurological review of systems (focal, headaches, seizures, other) Past Medical History Family History Infectious exposures/Risk factors for stroke History of skin, ophthalmologic, joint involvement, recurrent fevers
Physical Examination	Vital signs, peripheral pulses General and neurological examinations Rheumatologic assessment Neuropsychological assessment
Laboratory Investigation	<i>Markers of Inflammation:</i> CBC, CRP, ESR, IgG, C3, vWF <i>Prothrombotic Markers:</i> Protein S, C, ATIII, fibrinogen, plasminogen, homocysteine; factor V Leiden, PT gene mutations, lupus anticoagulant. <i>Autoantibodies:</i> ANA, ENA, dsDNA, ANCA, aPL, ACL (depending on the differential diagnosis: NMDAR, VGKC, GAD, GABA) <i>Infectious serology:</i> <i>B. burgdorferi</i> , VDRL, HIV, VZV
Lumbar CSF Analysis	OP, cell count, protein, glucose, IgG, OCB Cryptococcal antigen, VDRL, viral encephalitis register paired serum and CSF <i>B. burgdorferi</i> and VZV serology bacterial, fungal, TB cultures specific autoantibodies depending on the differential diagnosis
Neuroimaging	CT/CTA MRI/MRA with gadolinium and vessel wall imaging Cerebral angiography Brain SPECT PET/CT Doppler ultrasound
Tissue Biopsies	Brain and overlying meninges Skin, nerve, muscle as indicated

*Adapted from [115 and 128]. Abbreviations: CBC, complete blood count; ATIII, CRP: C-reactive protein, ESR, erythrocyte sedimentation rate, C3, C3 complement; ATIII, anti-thrombin III; VWF, Von Willebrand factor; ELISA, enzyme linked immunosorbent assay; CSF, cerebrospinal fluid; PT, prothrombin; LAC, lupus anticoagulant; ANA, antinuclear antibody; ENA, extractable nuclear antibody; dsDNA, double-stranded DNA antibody; aPL and ACL, anti-phospholipid and anti-cardiolipin antibodies; NMDAR, N-methyl-D-aspartate receptor; VGKC, voltage-gated calcium channel, GABA, gamma-aminobutyric acid; VZV, varicella-zoster virus; CT/CTA, computed tomography and angiography; MRI and MRA, magnetic resonance imaging and angiography; SPECT, single photon emission computed tomography; PET/CT, positron emission tomography and computed tomography; IgG, immunoglobulin G; VDRL, Venereal disease research laboratory; TB, tuberculosis; OCB, oligoclonal bands; GAD, glutamate decarboxylase; C3, complement component 3.

Differential Diagnosis

Numerous non-inflammatory conditions must be considered in the differential diagnosis of CNS vasculitis. One mimic of large vessel CNS disease described above is arterial dissection, an important cause of stroke which may extend intracranially more often in

children [5, 103]. The importance of differentiating FCA from intracranial dissection was recently highlighted by the description of four patients with classic FCA presentations but pathologic and wall imaging evidence of intracranial dissection [104]. Additional well defined, non-inflammatory childhood arteriopathies include Moyamoya disease or syndrome [105], post-radiation vasculopathy [106], and other congenital arteriopathies [42]. Reversible cerebral vasoconstriction syndrome (RCVS; Call-Fleming) has rarely been described in children [107]. Fibromuscular dysplasia (FMD) is different in children from adult FMD, and associated with arteriopathic stroke, systemic arteriopathy and hypertension [108].

Several conditions may also mimic small vessel vasculitis in children. Given the diverse nature of both the clinical and imaging findings, broad categories must be considered including demyelinating diseases such as acute disseminated encephalomyelitis, multiple sclerosis, toxin exposures, inborn errors of metabolism, hypertensive crisis, neoplasia, notably CNS lymphoma, and others. A difficult clinical distinction is made between small vessel vasculitis and an increasing number of autoimmune encephalitides. Patients with autoimmune encephalitis present with symptoms of headaches, personality changes, and other neurological findings with non-specific lesions on imaging, as described in small vessel vasculitis, however, the distinguishing features are normal cerebral angiography and different serum biomarkers and/or brain biopsy pathology [109]. Skip lesions reported in primary granulomatous angiitis of the CNS can further confound the diagnostic picture [110], however full-thickness, lesional biopsies minimize the possibility of false-negative results [43, 111].

Serologic Studies

Most children with cPACNS do not manifest systemic inflammatory markers as the disease process is isolated to the CNS. Acute phase reactants such as ESR, CRP, and vWF are often normal or only mildly elevated. Antinuclear antibody titers are also only variably elevated [13, 15, 112]. One single-centre, retrospective study of 62 children with cPACNS [41] found elevations in ESR in 51% of patients, CRP in 74%, IgG in 35%, anticardiolipin antibodies in 44%, without ANCA. Elevations of inflammatory markers were not predictive of outcome, progression, or disease type. Another single-centre cohort of patients with cPACNS [113] found that 65% of 39 patients with both small and large-medium vessel vasculitis had elevated vWF titers that correlated with disease activity. The findings of elevated levels of tumor necrosis factor (TNF)- α , interleukin (IL)-2, IL-6, and IL-8 in childhood AIS [114] suggests their potential usefulness in the laboratory evaluation of cPACNS. Secondary CNS vasculitis is generally suggested after a detailed history and physical examination. The presence of elevated non-specific inflammatory markers should direct the laboratory investigation to serologically-specific disease markers, particularly those that would dictate treatment such as SLE [52].

Cerebrospinal Fluid Analysis

CSF analysis is essential for excluding crucial considerations in the differential diagnosis such as infection [115]. Although often normal [13, 15, 48, 116], elevated opening pressure,

pleocytosis, and raised CSF protein have been described in both large and small vessel cPACNS [14, 15, 112]. Abnormal CSF was described in 39% (9/23) patients in a single-centre, retrospective study [41] of 62 children with cPACNS. Findings included non-specific or lymphocyte-predominant pleocytosis in 32% and the same proportion with elevated protein. Oligoclonal bands were absent. CSF markers were not associated with outcome or progression of disease. However, the numbers were too small to distinguish differences between subtypes of vasculitis.

Isolated case reports of children with PVA have shown mild CSF pleocytosis. [80] The detection of CSF anti-VZV IgG antibodies is possibly more sensitive than VZV PCR testing with some [117] suggesting the diagnosis can be excluded when CSF is negative for both. The use of an antibody index (AI) to better determine significant elevations of VZV antibodies in CSF has been proposed as more sensitive [118]. With the exact role of VZV in childhood arteriopathy yet to be determined, these findings and other isolated cases of infection-associated arteriopathy [89-91, 95] suggest that additional methods to define CSF biomarkers are required [102].

Neuroimaging

The diagnosis of a child with acute focal neurological deficits is stroke until proven otherwise. It requires urgent imaging in the form of CT or MRI depending on availability of scan and stability of the patient. Given the high incidence of arteriopathy in childhood stroke, angiography should be included in the initial imaging protocol [8]. For children being evaluated for subacute or progressive neurological changes such as headaches, cognitive or behavioral changes, MRI is the modality of choice.

Advanced cerebral vascular imaging modalities have increased the sensitivity of detecting and defining the unique features of childhood arteriopathies. CT, MR and conventional angiography are used to confirm arteriopathy in most children with large vessel arteriopathy. Inflammation is considered if stenosis, narrowing, or occlusion is seen without evidence of dissection and when associated with luminal irregularities or other indications of arterial wall disease. However, it is important to note that there are no validated imaging biomarkers of inflammation in childhood stroke [25]. CTA and MRA produce excellent images of first and second order cerebral arteries but resolution of smaller vessels is limited.

The diagnosis of large-medium vessel vasculitis according to the criteria of Calabrese and colleagues [46] requires demonstration of the angiographic findings of arteritis if brain biopsy is not feasible. Conventional angiography is the preferred modality for demonstrating specific vascular abnormalities. Banding or striae are key findings in large-medium vessel vasculitis (Figure 2D). Similarly, alternating areas of stenosis and dilatation in distal arterial beds are seen in small vessel cPACNS [24, 51]. Sensitivity is only moderate for predominantly distal, small vessel disease [47]. Conventional angiography which is very safe in the pediatric population [119] should be considered in children with AIS.

Less invasive vascular imaging modalities are preferable for serial surveillance of fluctuating disease or syndromes with high recurrence risk. When comparing MRA to conventional angiography, sensitivity and specificity for known angiographic abnormalities identified on MRA were 70% and 98% respectively in one study [47]. MRI and MRA have been evaluated in single centre cohort studies. All patients with abnormal conventional

angiography were found to have abnormalities on parenchymal MR imaging but only 71% had MRA abnormalities [120]. Conventional angiography is clearly more sensitive than MRA but angiography-negative cases are common in children [47]. MRA remains an essential tool for initial screening and serial follow-up over time.

Despite the low specificity of MRI for the detection of parenchymal lesions in small vessel vasculitis, a combined approach with other clinical markers may increase the diagnostic yield. Angiogram-negative cases often have parenchymal MRI abnormalities [41, 50, 120] including, supratentorial, asymmetrical, anterior circulation lesions of the white matter or deep gray structures [41, 120]. Imaging predictors of progressive vasculitis are multifocal, bilateral, and gray matter lesions, combined with multiple, bilateral, or distal vessel stenoses [41]. Recently introduced vessel wall imaging techniques including high resolution anatomical and blood sensitive sequences have been developed to help distinguish arterial pathology in adult CNS vasculitis [121-125]. Such approaches are not yet well described in children but carry the excellent potential to address the pathophysiology of CNS vasculitis. Case reports of FCA suggesting reversible wall enhancement have been published [126]. Recently described normal cerebral arterial wall enhancement may assist in defining abnormal patterns of stroke in children [127]. Further studies in this area could provide additional non-invasive imaging biomarkers of inflammation or other processes, as well as, the evolution of disease over time and response to treatment.

Diagnostic Tissue Pathology

Pathological confirmation of vasculitis is the gold standard of diagnosis, however obtaining required tissue may be difficult or unfeasible. Brain biopsy may be feasible and even diagnostic, however in small vessel cPACNS, MRA and cerebral angiography are usually normal. In children, a non-granulomatous predominantly T-cell lymphocytic vasculitis of small vessels is typically found in lesional and non-lesional biopsies of angiography-negative cPACNS. Occasional macrophages, polymorphonuclear cells, and eosinophils may also be present. Involved cerebral vessels in leptomeninges, cortical gray and subcortical white matter demonstrate intramural and perivascular inflammatory cell infiltrates [14, 15, 50, 112] with surrounding reactive changes [14]. Granulomatous angiitis of the CNS is distinctly uncommon in children [116]. Full-thickness combined leptomeningeal and cortical biopsy, ideally localized to an area of image-based disease is preferred when possible although non-lesional “blind” biopsies can incur significant diagnostic potential [43, 111]. Systemic or secondary vasculitides may offer additional tissue diagnostic options such as skin, muscle, or nerve biopsy in PAN, renal biopsy in GPA and IgAV [23], or salivary gland biopsy in Sjogren syndrome [55]. A more unified and systematic approach for obtaining and analyzing brain biopsy tissue is required and being developed.

TREATMENT

Recognizing the real possibility of vasculitis in children with stroke, published consensus guidelines [8] acknowledge consideration of anti-inflammatory or immunosuppressive

interventions but offer little direction. The tenets of childhood stroke treatment include acute neuroprotective care and antithrombotic therapies including antiplatelet or anticoagulation strategies, the latter particularly indicated in CSVT or cardiogenic AIS. A decision to couple such treatments with an anti-inflammatory intervention when primary or secondary cerebral vasculitis is suspected is more difficult. Perhaps the only clear indications for immunomodulation are strokes associated with confirmed systemic inflammatory disease or pathologically proven small vessel cPACNS. Published protocols for cPACNS [15, 43, 50] include six months of oral corticosteroids coupled with monthly pulses of intravenous cyclophosphamide followed by maintenance therapy employing azathioprine or other low dose maintenance therapy for an additional eighteen months. Alternative approaches may consider initial high-dose oral corticosteroids for three months [43, 128] and methotrexate and/or mycophenolate mofetil for long-term maintenance therapy [13, 51]. So while precise agents, dosing, and protocols remain to be determined, immunomodulation is clearly indicated in certain childhood vasculitic stroke syndromes.

Immunomodulation for large-medium cPACNS is more controversial. Early recurrence risk is high and children often progress in both arteriopathy severity and symptomatic ischemia in the days and weeks following diagnosis. With the ability of antithrombotic medications to prevent early recurrence unproven and likely modest, many will consider introduction of anti-inflammatory treatments, particularly in high risk patients. Steroids are most often used with reasonable extrapolation from historical adult stroke trials suggesting relative safety. Ease of administration, rapid onset of action, and even positive effects on cerebral perfusion pressure merit consideration. Time courses are not well established but may parallel the natural history of cPACNS, TCA, or PCA where disease activity is expected to diminish over months. Patients with PVA have also been treated with short courses of intravenous methylprednisolone and two weeks of acyclovir [67, 129, 130], although some have questioned the benefit of such an approach in VZV-associated stroke [80]. Others [66, 84] reason that acute antiviral treatment is unnecessary as acyclovir only suppresses active viral replication while an effect on autoimmune reactions by dormant virus seem unlikely [118].

The management of secondary CNS vasculitis focuses on AIS in the context of the associated systemic inflammatory disorder. Combination therapy employing corticosteroids and cyclophosphamide is appropriate for stroke in association with IgA, as is intravenous high-dose methylprednisolone followed by maintenance oral corticosteroid tapered over 3 months for CSVT in BD [38]. Stroke prevention in TAK focuses on prevention of progression of disease in the aorta and its branches employing disease modifying agents and surgical interventions with grafting and stenting if necessary [131-133].

Rehabilitation should be addressed based upon a model of early multidisciplinary assessment and intervention to prevent secondary complications of AIS and reduce disability and financial burden according to published guidelines [134]. This typically entails a traditional therapy program of exercises to promote muscle strength and development, the integration of assistive devices such as orthotics and splints. [135] Management of associated comorbidities includes anticonvulsants for symptomatic epilepsy, behavioral management notably for attention deficit hyperactivity disorder, and neuropsychological testing and support for educational and vocational needs to optimize outcomes.

CONCLUSIONS

The most common cause of stroke in healthy children is arteriopathy. The expansion of knowledge in the recognition, diagnosis, and treatment of pediatric vasculitic cerebral arteriopathy witnessed in the past decade carries important implications for current approaches to diagnosis and treatment while defining a clear need for improvements in both.

ABSTRACT

The vasculitides are diseases characterized by inflammation of blood vessels and inflammatory leukocytes in vessel walls. There is an increased propensity for ischemic stroke as a result of compromise in vessel lumina and distal tissue ischemia, with hemorrhagic stroke and aneurysmal bleeding due to loss of vessel integrity.

INTRODUCTION

The vasculitides are diseases characterized by inflammation of blood vessels and inflammatory leukocytes in their walls. There is an increased propensity for ischemic stroke as a result of compromise of in vessel lumina and distal tissue ischemia, and hemorrhagic stroke and aneurysmal bleeding due to loss of vessel integrity. The 2012 Revised Chapel Hill Consensus Conference (CHCC) [1] nomenclature provides systemic nosology and a categorization of primary and secondary vasculitides. Central nervous system (CNS) involvement and stroke both occur in the single-organ vasculitic (SOV) syndrome primary CNS vasculitis (PCNSV) [2], as well as, due to limited or multiorgan manifestations of primary systemic vasculitides [1].

PRIMARY CNS VASCULITIS

With several proposed diagnostic schemes for PCNSV over the years [3-5], the combination of clinical and histopathological findings derived from cerebral angiography and leptomeningeal and brain biopsy remains the recommended method of definite diagnosis [6]. This approach facilitates the identification of clinicopathologic subtypes such as those with persistent focal deficits and stroke [2] or intracranial hemorrhage [7] from the reversible cerebral vasoconstriction syndrome (RCVS) [8] that may mimic true vasculitis but does not require cytotoxic therapy.

Historically, Younger and colleagues [3], who described four patients with granulomatous angiitis of the brain histopathologically manifesting necrotizing vasculitis of arteries and veins of varying caliber in conjunction with giant cells and epithelioid cells, noted non-focal symptoms of headache and mental change, followed by focal weakness, seizures, and fatal coma in all four patients. Focal weakness with a stroke onset was noted in two (Patient 1 and 3) of the four patients, Patient 1 of whom had onset of lethargy, focal ptosis and hemiparesis had predominant anterior (ACA), middle (MCA), posterior cerebral artery (PCA) and basilar artery involvement at postmortem examination. Patient 3, who presented with hemiparesis, ataxia, and dysarthria, was later found to have predominant small leptomeningeal artery and vein involvement. Altogether, 15% of 78 patients overall had focal weakness with stroke onset compared to 42% who presented with focal deficits during the course of the illness.

In the same year, 1988, Calabrese and Mallek [4] described eight patients with classic angiographic or histopathologic features of PCNSV or so called primary angiitis of the CNS (PACNS), and reviewed the literature of 40 literature cases. One (patient 2) [9] who presented with the clinical diagnosis of isolated angiitis of the CNS (IACNS) defined by classical angiographic features, had a clinical onset of transient weakness that progressed to fixed hemiparesis, nonfluent aphasia, alexia, and agraphia with later stabilization after combination prednisone and cyclophosphamide therapy.

Birnbaum and colleagues [5] proposed changes to the criteria of Calabrese and Mallek [4] to include a definite diagnosis of PCNSV only after tissue biopsy confirmation, noting strokes or persistent deficits in less than 20% of patients at onset, and with only about 28% of symptoms overall related to large cerebral vessel involvement. Salvarani and co-workers [2] noted that persistent neurological deficit or stroke and headache were the commonest initial symptoms affecting 68% of 101 patients so studied with PCNSV defined by diagnostic criteria similar to those suggested earlier [4]. Cerebral infarction was noted on magnetic resonance imaging (MRI) of the brain in 53% of patients that were multiple in appearances in 85%, bilateral in 83%, and involved the cortex and subcortex in 63%. Overall, their appearance suggested large-artery, branch-artery or small-artery distributions. Intracranial hemorrhage was noted in 8% of patients. Gadolinium enhancement was found in one-third of patients, a quarter of which demonstrated gadolinium enhancement of the meninges.

Montefort and co-workers [10] described a 57-year-old man with brain-biopsy confirmed PCNSV and a 2-month history of right arm weakness and numbness superimposed on a history of left-sided headache and intermittent visual field loss. Brain MRI showed evidence of cortical infarction across more than one vascular territory with signal changes consistent with hemorrhage in the left basal ganglia and parieto-occipital lobe. There was angiographic

evidence of irregular narrowing and aneurysmal dilatation of the left terminal carotid artery which stabilized without new areas of new infarction after treatment with intravenous pulsed cyclophosphamide and corticosteroids followed by azathioprine. The neuroimaging features of this patient are shown in Figures 1 to 4, as well as, in a similarly affected patient in Figures 5 and 6.

Figure 1. Primary CNS vasculitis. T₂-weighted MRI of the brain demonstrates left frontal and parieto-occipital lobe areas of infarction. Reproduced with permission from [10].

Figure 2. Primary CNS vasculitis. T₁-weighted MRI of the brain showed left basal ganglia haemorrhage. Reproduced with permission from [10].

Figure 3. Primary CNS vasculitis. T1-weighted MRI of the brain demonstrates gyral enhancement after intravenous administration of gadolinium before treatment (A), that resolves after immunosuppressant therapy (B). Reproduced with permission from [10].

Figure 4. Primary CNS vasculitis. Cerebral angiography shows a sessile internal carotid artery aneurysm. Reproduced with permission from reference 10.

Figure 5. Primary CNS vasculitis. T₂-weighted MRI of the brain shows bilateral cerebellar hemispheric infarcts and abnormal signal hyperintensities before treatment (A) that resolve after immunosuppressant.

Figure 6. Primary CNS vasculitis. Cerebral angiography shows widespread vessel irregularity and beading.

PRIMARY LARGE VESSEL VASCULITIS

Giant cell arteritis (GCA) and Takayasu arteritis (TAK) are prototypical large vessel granulomatous vasculitides (LVV) that involve the aorta and its major branches however any size artery can be affected [1]. Imaging studies and fluorescein angiography studies have shown that ocular involvement in GCA can affect not only ophthalmic, but also medium caliber retinal arteries and multiple ciliary arteries and their smaller branches; blindness may result not only from LVV but injury to smaller ophthalmic branches [1]. Whereas GCA has a predilection for branches of the carotid and vertebral arteries and age at onset older than 50 years, often associated polymyalgia rheumatica, TAK is typified by involvement of proximal subclavian and carotid arteries and onset by age 40 years or less. Neuroimaging studies employing ultrasonography, high-resolution MRI, and ¹⁸fluorodeoxyglucose-positron emission tomography (FDG-PET) imaging are useful modalities to depict superficial cranial and extracranial vessels, and large vessel subclavian and aortic involvement in GCA and TAK [11].

CNS involvement in GCA, which results from thrombosis of the carotid and vertebral arteries rather intracranial arteritis, affects vessels that contain elastin, more specifically the internal elastic lamina that is absent from intracranial vessels more than 5 millimeters beyond the point of dural perforation. Reich and colleagues [12] and Gonzalez-Gay and co-workers [13] summarized the literature pertaining to stroke and GCA. Reports of CNS involvement were erroneously attributed to intracranial GCA rather than PCNSV [14-16]. Hellenhorset and colleagues [17] noted CNS events including stroke in 7.4% of 175 patients with confirmed GCA, as well as, and one patient with massive cerebral hemorrhage, two with stroke, and six with occlusive disease of the aortic arch. Caselli and colleagues [18] noted transient ischemic attacks or stroke in 7% of 166 patients with biopsy-proven GCA, among whom four had events in the vertebrobasilar system, and eight affected the carotid arterial system. With approximately 30% of patients manifesting neurological findings, the commonest of which were neuropathies of the arms and legs according to Caselli and colleagues [18], Salvarani and colleagues [19] observed that transient ischemic attacks or stroke in the territory of the carotid or vertebrobasilar arteries were less common neurological findings.

Gonzalez-Gay and co-workers [13] ascertained the frequency of cerebrovascular accidents (CVA) in association with GCA among 239 patients in a multicenter retrospective analysis to assess the features, therapeutic response, and predictors of visual loss and CVA. Eight patients (3%) developed CVA, equally divided between the vertebrobasilar and carotid territories. The ischemic events were preceded by other symptoms of arteritis by a median of 1.5 months, and were more frequent in those with visual involvement, especially permanent visual loss. Two patients with vertebrobasilar stroke died within one month despite aggressive corticosteroid therapy. Stepwise logistical regression analysis revealed visual loss and jaw claudication as the predictors of CVA.

Kerr and colleagues [20] summarized the clinical, laboratory and treatment responses of 60 patients with Takayasu arteritis (TAK) based upon the presence of symptoms and signs of ischemic, inflammatory large-vessel disease as well as supportive arteriographic findings, so noting 10 (17%) patients with either transient ischemic attacks or CVA, and carotid or vertebral artery disease, eight of whom corresponded to the neurological deficit. One of the

remaining two had hypertension, whereas the other patient had isolated stenosis of the innominate artery. Riehl [21], and Riehl and Brown [22] reported the clinical and pathological features of six patients with TAK noting widespread arteritis that not only involved the aortic arch and its tributaries by clinical and angiographic studies, but many other medium-, and large-sizes vessels. One patient with TAK manifested clinical and histopathological evidence of CNS involvement. That patient, a 43-year-old woman who presented with rapidly disappearing blood pressure and complained of spells of progressively worsening dizziness and dimness of vision, died of severe congestive heart failure. At postmortem examination, there was severe stenosis of the distal aorta, thrombosis of an aortic arch graft with nearly complete obstruction of all the great vessels by granulomatous panarteritis, as well as vasculitic involvement of the proximal portion of the left MCA, both PCA arteries, and anterior third of the basilar artery. There was massive infarction of the left temporoparietal region, the left half of the midbrain, brain stem, and cerebellum.

PRIMARY MEDIUM VESSEL VASCULITIS

Polyarteritis Nodosa (PAN) and Kawasaki disease (KD) are prototypical medium vessel vasculitides (MVV). Although any size of artery may be affected in this category, PAN is associated with necrotizing arteritis of medium or small arteries without glomerulonephritis or vasculitis in arterioles, capillaries, or venules; however, it is not associated with anti-neutrophilic cytoplasmic antibodies (ANCA) [1]. By contrast, KD is an infantile or childhood disorder that is associated with the mucocutaneous lymph node syndrome, predominantly affecting medium and small arteries, occasionally coronary, the aorta, and other large arteries [1].

Among early postmortem series of PAN, Middleton and McCarter [23] noted CNS involvement due to arteritic lesions in one (Patient 1) that consisted of an occasional small artery. Brain tissue was not examined in one patient (Patient 2) and was not mentioned in another (Patient 3). Kernohan and Woltman [24] summarized the clinicopathological aspects of adult PAN in six patients studied at postmortem examination, estimating CNS involvement associated with stroke in about 8% of cases, and a combination of acute and chronic lesions that correlated with known exacerbations. In three patients, the peripheral nervous system (PNS) was widely involved at onset and at postmortem examination in addition to systemic involvement typically sparing the CNS, while in one patient, the PNS and CNS was involved alone. That patient was a 32-year-old man with onset of left arm and leg hemisensory loss and headache that progressed to paralysis. At postmortem examination there was marked thickening and near complete obliteration of the right MCA, less so on the left side, and obstruction of the right PCA by a recent thrombus, with a normal PCA on the left. Microscopic analysis showed subacute and chronic lesions of PAN.

According to Guillevin and co-workers [25], CNS involvement is rare but motor deficiencies, stroke and brain hemorrhages can occur as well as cognitive disturbances associated with abrupt memory loss and scattered T₂-weighted hyperintensities on brain MRI suggestive of cerebral vasculitis. CNS involvement including stroke was noted in 9.6% of 115 patients in the FVSG [26] with hepatitis B virus (HBV)-PAN between 1972 and 2002. The FVSG treatment protocol for HBV-PAN generally included cyclophosphamide,

corticosteroids and plasma exchange (PE), alone or together, followed by vidarabine, interferon-alpha (INF- α), or lamivudine, depending upon the time of diagnosis and different treatment protocols available [27-29]. So treated, nine patients (9.7%) who achieved remission subsequently relapsed, one of whom died of stroke, but the relationship between PAN and stroke could not be established. A retrospective study of 348 adult patients registered in the FVSG [30] who satisfied criteria for the diagnosis of PAN between 1963 and 2005 noted CNS involvement including stroke in 4.6% of patients overall, with a relatively equivalent frequency among patients with and without HBV-related illness.

PRIMARY SMALL VESSEL VASCULITIS

Small vessel vasculitis affects intraparenchymal arteries, arterioles, capillaries, and venules however medium-sized vessels and veins may also be involved [1]. Two major categories of SVV include ANCA-associated vasculitis (AAV) characterized by necrotizing vasculitis with few or no immune complex (IC) deposits predominantly affecting small arteries, arterioles, capillaries, and venules associated with myeloperoxidase (MPO) ANCA or proteinase 3 (PR3). IC vasculitis is characterized instead by marked vessel wall deposits of immunoglobulin (Ig) and complement. Granulomatosis with polyangiitis (GPA) (Wegener granulomatosis [WG] type), eosinophilic granulomatosis with polyangiitis (EGPA) [Churg-Strauss syndrome [CSS]], and microscopic polyangiitis (MPA) (microscopic polyarteritis) are prototypical AAV, while cryoglobulinemic vasculitis (CV), IgA vasculitis/Henoch-Schönlein purpura (IgAV/HSP), and hypocomplementemia urticarial vasculitis (HUV) associated with C1q antibodies comprise the IC vasculitides; HSP/IgAV is predominantly a disorder of childhood.

ANCA-ASSOCIATED VASCULITIS

Granulomatosis with Polyangiitis

GPA is characterized by necrotizing granulomatous inflammation of the upper and lower respiratory tracts and necrotizing vasculitis of small to medium arteries, arterioles, capillaries, veins, and venules together with glomerulonephritis [1]. Drachman [31] described a patient with one month of headache that awakened him from sleep followed by rhinitis, nasal obstruction, epistaxis, mononeuropathy multiplex, confusion and hypertension. Active arteritis and necrotizing granulomata were found in the brain but not in peripheral nerves. Based upon the observations in a single postmortem studied patient, cerebral involvement according to Drachman [31], depended upon a combination of four separate entities, 1) Frank vasculitis of larger arterial branches particularly over the surface of the brain as demonstrated in his patient report; 2) Ischemia in portions of the territory supplied by the affected vessels; 3) Subarachnoid hemorrhage and hypertensive encephalopathy evidenced by microscopic infarcts in close relation to arteries with fibrinoid impregnation of their walls; and 4) Meningeal infiltration by mononuclear cells. Nishino and colleagues [32] described neurological involvement in 34% of 324 consecutive patients with GPA at the Mayo Clinic

between 1973 and 1991 classified according to the American College of Rheumatology (ACR) [33] that included peripheral neuropathy in 16% compared to cerebrovascular events in 4% at some time in the course of illness, however rarely if ever at presentation. Of five patients with presumed clinical vasculitis, cerebral angiography was negative in two. Of twelve patients studied at postmortem examination, findings of vasculitis were detected in only two patients. Fauci and colleagues [34] noted nervous system involvement in 22% of 85 patients, 10 patients (12%) of whom had CNS involvement including strokes at some point in the illness although not specifically mentioned at presentation. Moore and co-workers [35] estimated the frequency of neurological abnormalities of GPA at 23% to 50%, citing possible mechanisms of neural dysfunction due to inflammation from primary sites, remote granuloma formation, and vasculitis. Drachman [31] opined that contiguous extension of necrotizing granulomas might account for 24% of all neurological complications including those of the CNS.

Extensive cerebral infarction in the territory of the bilateral ACA was ascertained in a 67-year-old man with frontal headache that preceded detection of a large midline frontal mass lesion on computed tomography (CT), and known biopsy-proven GPA and granulomatous vasculitis of the nasal cavity, liver and kidney. Postmortem examination showed cerebral infarction in the areas supplied by A2 branches of both ACA, with occlusion of large sized ACA vessels by organized mural thrombi, and fibrinoid necrosis in the arterial branches. There was similar vasculitis with multinucleated giant cells involving small arteries and veins diffusely in the frontal region of the brain suggesting contiguous spread from granulomatous nasal cavity lesions. Hoffman and colleagues [36] retrospectively assessed 180 patients with GPA for 6 months to 24 years noting nervous system involvement in 23% of patients, including CNS involvement and stroke in 8% of patients. A prospective analysis of clinical, electrophysiologic, radiologic, and serologic data of 128 GPA patients over 19 months [37] noted CNS involvement in 7%, the latter including granulomatous infiltration of frontobasal cortex arising from adjacent paranasal sinus granulomas, cerebral vasculitis, stroke, vascular myelopathy, and meningeal granulomatosis.

Microscopic Polyangiitis

Microscopic polyangiitis is a necrotizing AAV vasculitis with few or no IC deposits and commonly associated glomerulonephritis without granulomatous inflammation [1] Neither Davson and colleagues [38] who separated fourteen postmortem studied patients from 1934 to 1947 with MPA into two groups based upon the presence of severe widespread glomerular damage, nor Wainwright and Davson [39] who described MPA among 6 post-mortem studied patients from 1947 to 1948, mentioned CNS involvement, stroke onset or histopathologic brain involvement. Nor was there mention of patients with CNS involvement by Adu and co-workers [40] among 43 patients with renal histologic evidence of MPA. Savage and co-workers [41], who studied 34 patients with MPA, all of whom presented with clinical evidence of a systemic SVV predominantly affecting the skin and musculoskeletal system associated with focal necrotizing glomerulonephritis, cited CNS involvement at presentation in 18% of patients without specific mention of stroke. Serra and colleagues [42], who reported the presentation, histopathology and long-term outcome of 53 patients with MPO from 1965 to 1981, cited CNS involvement at presentation in 15% of patients, the findings of

which included stroke, convulsions, headache, confusion and drowsiness. Guillevin and co-workers [43] who reported the clinical and laboratory findings in 85 patients from the FVSG with MPA from 1969 to 1995, noted CNS involvement in 11.8% of patients at presentation and in 3% of 29 patients who experienced a relapse; however, there was no specific mention of stroke. Gayraud and co-workers [44] analyzed four prospective trials that included 278 patients with PAN, MPA and EGPA from 1980 to 1993, that reported stroke occurrence that accounted for 85 deaths. Villiger and Guillevin [45], who reviewed several retrospective European patient cohorts [40-43, 46], cited CNS involvement that included subarachnoid hemorrhage, cerebrovascular disease, meningitis and diffuse brain injury. Ben Sassi and colleagues [47] described intracerebral hemorrhage secondary to necrotizing vasculitis that similarly involved the nerves and muscles, citing three additional patients with hemorrhagic stroke due to MPA [48-50]. Ahn and colleagues [51] studied 55 patients with MPA, 69% of whom demonstrated perinuclear ANCA by immunofluorescence (IF) or MPO ANCA-seropositivity, noting CNS involvement in 5 (9.1%), none of whom developed end-stage renal disease. and one of whom died at follow-up without known autopsy.

Eosinophilic Granulomatosis with Polyangiitis

EGPA is a necrotizing vasculitis involving small to medium vessels that differs from GPA by the presence of eosinophil-rich necrotizing granulomatous inflammation of the respiratory tract in association with asthma and eosinophilia, and ANCA seropositivity when glomerulonephritis is present [1]. Churg and Strauss [52] described the clinical and postmortem findings of thirteen patients with asthma, fever, and hypereosinophilia. This was accompanied by eosinophilic exudation, fibrinoid change, and granulomatous proliferation that constituted the so called allergic granuloma. The latter were found within vessels walls and extravascular connective tissue of major organ systems. CNS organ manifestations were described in 8 (61.5%) of patients, and the cause of death in 3 patients who sustained cerebral hemorrhage or subarachnoid hemorrhage. Chumbley and co-workers [53] described 30 asthmatic patients from the Mayo Clinic over the period from 1950 to 1974 with necrotizing vasculitis of small arteries and veins, extravascular granulomas and infiltration of vessels and perivascular tissue eosinophilia. Lanham and colleagues [54], who emphasized that the combination of necrotizing vasculitis, tissue infiltration by eosinophils and extravascular granulomas suggested by Churg and Strauss [52] occurred contemporaneously in only a minority of patients, and that such histological findings could be encountered in other granulomatous, vasculitic and eosinophilic disorders in the absence of clinical asthma, allergic rhinitis, sinusitis, pulmonary infiltrates, and cardiac involvement pathognomonic of EGPA, noted CNS involvement in 25% of cases. Cerebral hemorrhage and infarction as a consequence of vasculitis or hypertension was a major cause of morbidity and mortality, accounting for 16% of deaths.

Sehgal and colleagues [55] noted neurological involvement among 14 patients with the clinical diagnosis of EGPA, three of whom had cerebral infarction two to fifteen years after initial diagnosis. The first patient was a 68-year-old woman with a stroke involving the territory of the MCA manifested as hemiparesis and aphasia. The second patient was a 34-year-old man with a right parietal lobe infarction pursuant to embolization of a left ventricular thrombus, manifested incoordination and hemisensory loss of the arm. The third patient was a

62-year-old woman with a thalamic infarction who manifested hemibody sensory loss. Guillevin and co-workers [56] studied 96 patients with EGPA between 1963 and 1995, noting ischemic stroke onset in 6 (6%) by brain computed tomography (CT). Mouthon and colleagues [57], reported 38 patients with EGPA from 1978 to 1998, citing CNS involvement in 3 elderly patients (7.9%) in whom CNS vasculitis was suggested by MRI of the brain in only one patient. Among 383 patients with EGPA enrolled in the FVSG Cohort [58] employing the definition of the ACR [59], CNS involvement was noted in 20 (5.2%) of patients at onset, with two-fold greater frequency of ANCA-seropositive serology than those ANCA-seronegative, but no specific mention of stroke frequency.

IMMUNE COMPLEX VASCULITIS

Cryoglobulinemic Vasculitis

Cryoglobulinemic vasculitis (CV) or CryoVas is typified by cryoglobulinemic IC deposited along small vessels predominantly arterioles, capillaries, veins, and venules in association with serum cryoglobulins. In mixed cryoglobulinemia (MC), the immune complex is composed of IgM and polyclonal IgG with rheumatoid factor activity often in association with hepatitis C virus (HCV) infection. Disease manifestations of cryoglobulinemia was noted in 206 of 443 (47%) patients [60] that included palpable purpura, 12 (6%) of whom had CNS involvement; HCV Infection was the main etiologic factor noted overall in 75% of the 443 patients. A concomitant autoimmune disorder was noted in 24%, hematologic disease in 7%, and essential cryoglobulinemia in 11% of the patients overall. The original patient described by Lerner [61], a 56-year-old man who presented with chest pain, purpuric rash and a cold precipitating serum protein, did not have symptoms or postmortem findings referable to the nervous system. Marshall [62] noted widespread cerebral purpura with hemorrhage ascribed to occlusion of small blood vessels by eosinophilic protein precipitates that correlated with the clinical presentation of progressively fatal coma.

Abramsky and Slavin [63] described three patients with MC and CNS involvement. The first was a 55-year-old woman with anarthria, hyperreflexia, bilateral Babinski signs and progressively fatal coma, who was later found at postmortem to have multiple thrombotic occlusions of small intracerebral blood vessels with adjacent foci of ischemia and marked demyelination. The second patient was a 50-year-old woman, who presented with a Wallenberg syndrome and was found to have MC with occlusion of the left posterior inferior artery at angiography. The third patient, a 50-year-old woman who presented with right hemiparesis and pyramidal signs, was found to have a cryoprecipitate and occlusion of the left MCA.

Gorevic and colleagues [64] summarized the clinical aspects of long-term followup of 40 patients with MC noting incidental CNS involvement at postmortem examination and a fatal stroke in another patient. Petty and co-workers [65] described a 35-year-old woman with type II cryoglobulinemia, headache, purpura, and seizures who was found to have multiple areas of T₂ and proton density signal abnormalities in the cerebral and cerebellar hemispheres, with a gyral pattern of enhancement in the cerebral cortex, a nodular pattern of enhancement in the

cerebellum, and early cortical infarction on right frontal brain biopsy without vasculitis; cerebral angiography was normal. HCV RNA was detected by polymerase chain reaction (PCR). Ince and colleagues [66] described a patient with paranoid psychosis and MC who was found to have right basal ganglia hemorrhage and multifocal small vessel occlusions by amorphous bland protein plugs and abundant Russell bodies present in arterioles and venules with relative sparing of capillaries.

Stroke was the presenting feature of CNS involvement in MC among two patients with lacunar infarcts and associated subcortical white matter changes on brain MRI [67, 68], and in one patient with a temporal arteritis-like syndrome with associated ischemic cerebral infarction [69]. Cacoub and co-workers [70] compared the features of patients with HCV examined for systemic vasculitis manifestations of PAN or MC noting two patients with cerebral vasculitis in the former versus none in the latter. Cacoub and colleagues [68] described CNS involvement in three patients with HCV infection and MC, one of whom was found to have a hemorrhagic lesion of the external capsule in association with pontine T₂ hyperintensities and parietal lobe infarcts. A second patient had a hemorrhagic occipital lobe lesion in association with cerebellar infarction and abnormal periventricular hyperintensities. A third patient had abnormal white matter hyperintensities.

Ferri and colleagues [71] studied the demographic, clinical, serologic features and survival of 231 patients with MC seen between 1972 and 2001, noting widespread vasculitis involving small- to medium-sized arteries, capillaries and venules with two or more visceral organs including the kidney, gut, and lung, noting no CNS manifestations of MC with exception of focal dystonia during interferon treatment in one patient [71]. Filipini and colleagues [72] reported a 63-year-old woman with acute severe encephalopathy HCV-related MC, dysarthria and hemiplegia. Frago and co-workers [73] reported a 35-year-old woman with dysarthria, left facial and left limb hemiparesis and hemisensory loss with MC in whom MRI showed ischemic lesions in the tail of the right caudate nucleus, corona radiata and posteromedial putamen. Casato and co-workers [74] reported the CNS findings in 40 patients with HCV-related CV in a multicenter, case-control study using MRI and neuropsychological testing. Although none evidenced cerebral infarction, small white matter lesions were found in all HCV-related MC subjects, a higher mean number of white matter intensities compared to HCV and healthy controls.

Terrier and co-workers [75] analyzed the data of 242 patients registered in the CryoVas survey ascertaining CNS involvement in 5 (2%) patients without specifying whether stroke was encountered. Terrier and Cacoub [76] reviewed CNS findings in HCV-seronegative and seropositive MC in CryoVas noting 2 (0.7%) patients among the former with CNS involvement, compared to 9 (5%) patients in the latter group evidencing CNS involvement but without further mention as to presence of stroke in any of the patients.

Hypocomplementemic Urticarial Vasculitis/C1q

Hypocomplementemic urticarial vasculitis/C1q presents with recurrent attacks of erythematous, urticarial and hemorrhagic skin lesions lasting up to 24 hours at a time, associated with recurrent attacks of fever, joint swelling, and variable abdominal distress. Circulating hypocomplementemia and C1q antibodies are associated with necrotizing SVV in skin biopsy tissue affecting arterioles, capillaries, and venules [1]. Apart from orbital

pseudotumor with ptosis, diplopia, and headache in one patient with HUV syndrome, there was no mention of CNS involvement or stroke in a review of 18 patients with HUV/C1q [77]. Nor was stroke mentioned in a review of four patients studied at postmortem examination with HUV/C1q [78]. Buck and colleagues [79] cited rare CNS manifestations in HUV/C1q including aseptic meningitis, pseudotumor cerebri, transverse myelitis but no mention of stroke or cerebral vasculitis. Grotz and colleagues [80] did not mention stroke or CNS vasculitis in a case report and review of the literature of HUV/C1q. In a review of HUV/C1q, Davies and Brewer [81] cited CNS involvement as “very rare”, attributing development of pseudotumor cerebri to vasculitis of the venous sinus system. Ludivico and colleagues [82] suggested that chronic pseudotumor cerebri in their patients was a diagnosis of exclusion and possibly related to chronic corticosteroid use, but did not cite patients with cerebral vasculitis or stroke.

Chapter 78

STROKE AND PULMONARY EMBOLISM OUTCOMES OR COMPLICATIONS ASSOCIATED WITH ICD DEVICE IMPLANTATION

Kanhaiya L. Poddar and Samir Kapadia*

Cleveland Clinic, Cleveland, OH.

ABSTRACT

Pacemaker and implantable cardioverter defibrillator device use has increased exponentially since their introduction. The devices and their placement process, in large part intravenous, make them susceptible as a nidus for thrombus formation and subsequent embolization to the pulmonary system or to the brain through patency in the interatrial septum. Available data examining this association and the role played by other clinical risk factors are divided. Through this chapter, we provide a comprehensive review and understanding of available evidence about the embolic risk associated with implantation of such devices and associated risk factors, mainly the PFO. We also discuss the various treatment options, both medical and interventional, with respect to risk of stroke or pulmonary embolism.

Keywords: pacemaker, implantable cardioverter defibrillator, stroke, transient ischemic attack, patent foramen ovale, atrial fibrillation

INTRODUCTION

During the early period of transvenous catheter implantation, unexpectedly few cases of embolism were reported. The ‘look out’ for adverse events in patients with implanted intravenous lead mainly centered around the complications associated with the mechanical

* Corresponding author: Samir Kapadia, M.D., Section Head, Invasive/Interventional Cardiology, Department of Cardiovascular Medicine, J2-3, Heart and Vascular Institute, Cleveland Clinic, 9500 Euclid Avenue, Cleveland, OH 44195, Telephone: (216) 444-6735, Fax: (216) 445-6176, Email: kapadis@ccf.org.

properties, such as electrode displacement, myocardial perforation, electrode fracture, pulse generator extrusion, infection, generator failure, electrode induced arrhythmia, etc. [1-4] The absence of literature about possible thrombus/embolic complications associated with device implantation attracted an editorial By Dr. Kurt Amplatz [5] in response to an article titled 'Clotting on the outer surfaces of vascular catheters,' an experiment on dogs showing a possible thrombogenic property of catheter implantation in vivo.[6] Two months later in 1968, the first case of embolization followed by pulmonary infarction due to thrombus formation around the catheter in a human was reported by Prozan GB et al.[7] In the absence of any other predisposing factor for pulmonary thromboembolism (PTE) in that patient, the needle of suspicion went to frequent sepsis associated with the catheter material as earlier observed from the use of catheter (of similar material) for a ventriculo auriculostomy procedure in children.[8, 9] This was followed by another case, where the possibility of emboli from the right side of the heart was suspected, instead of only the peripheral veins, as envisaged until that time.[10] Following these two cases, an association between device implantation, resulting in a foreign body being left *in situ* predisposing the mechanism responsible for embolic risk, and stroke/pulmonary embolism (PE) resulting in life threatening complication was visualized.

Unlike PE, the stroke associated with right heart occurs via atrial septal defect (ASD), mainly the most common defect, patent foramen ovale (PFO). This anatomic entity was first described in 1564, and its role as conduit for passage of emboli was brought to attention in 1877 in an autopsy study. Any relation of right heart device associated with stroke is viewed in conjunction with the presence of PFO. The role of PFO in stroke, especially the cryptogenic stroke, has been matter of long debate. More so with the advent of PFO closure devices which promised to reduce the stroke risk in patients with PFO. Hence, the discussion about stroke associated with device implantation may be conveniently divided into two major parts. First, the role of the pacemaker or implantable cardioverter defibrillator (ICD) device, its components or its placement as the source of embolus, and second, the PFO is believed to act as a conduit for passage of emboli through the shunt resulting in adverse neurological events.

DEVICE AND THROMBOGENIC RISK

A pacemaker or ICD device is required to provide required electrical stimulation in the form of cardioversion, defibrillation or pacing of the heart. For the sake of simplicity, we include all such devices which require a lead/extension in the right heart. These include ICD, automated implantable cardioverter defibrillator (AICD), pacemakers and others.

The insulation material covering the leads is the part of the device which can directly cause thrombogenic activity and act as a foreign body directly in contact with blood. Lagergren H et al. in mid 1960s, described the phenomenon of deposition of fibrin over the leads within 12 hours of implantation.[11] The incorporation of the lead within venous tissue was found to be prominent at the curves at the superior vena cava and entrance in the right atrium. At this time, polyethylene material was used as insulating material which was gradually replaced by silicone and polyurethane (introduced in 1979).[12] The later

transformation to other insulating materials occurred because of better bio stability and mechanical properties associated with the new material, rather than due to the risk of thrombus formation and embolism. Presently, a combination of polyurethane, silicone and fluoropolymer materials is used to manufacture the lead insulation. The change in lead materials answered many questions about bio-mechanical issues associated with device implantation, but evidence regarding the changes to the thrombogenic potential has been lacking. While the thromboresistance was reported to be comparable between silicone and polyurethane leads in early study [13], a comparative thrombogenicity study later done on pigs by Palatianos GM et al. found polyurethane to be more thromboresistant as compared to silicone.[14] Nevertheless, there was no evidence showing the new materials in anyway behaved worse than the older polyethylene material, and not surprisingly, newer materials got wider acceptance and gradually replaced the older insulation material.

Theoretically, the procedure of insertion of a cardiac lead does seem to fulfill the three criteria of Virchow's triad, i.e., injury to vessel wall, possible flow stasis and hypercoagulability, which predispose the patient to a thrombotic event. While the first two components are part of the procedure and its consequence, the third (hypercoagulability) criterion has been documented through studies.[15, 16] Even though symptoms of pulmonary embolism can be seen in only 0.6% to 3.5% of patients, the incidence of asymptomatic thromboembolism can be as high as 48%, often in older patients and those with congestive heart failure, ischemic and valvular disease.[17-20] In earlier studies, venous thromboembolism (VTE) was reported after insertion of pacemaker lead/wires.[12, 20-26] But those earlier studies were either case reports or studies with a limited number of patients and lacking multivariate analysis. Importantly, even though these studies point towards development of prothrombotic events in such patients, it has not been shown to result in thrombosis and thromboembolism.

As for the thrombogenic risk of intravenous leads, there is broad consensus on a few basic points. Platelet deposition and intravascular coagulation occur early after pacemaker implantation and symptomatic embolism is a rare occurrence in patients undergoing implantation, though subclinical/asymptomatic findings or venous obstruction/thrombosis can be observed with varying frequency during autopsy or with echocardiography.[27-30] Harcombe et al. studied 2,621 patients from 1984 through 1994 and followed them for at least one year to study various complications. They reported a 'miscellaneous' complication rate of only 0.3% (7 of 2,621) with no specific embolic complications.[31] But the study was designed to mainly look for complications such as infection and other lead structure associated complications. Lead infection can be an additional source of emboli formation in patients with intravenous cardiac lead implantation, with as many as 27% of patients reported to have pulmonary embolism and 14% reported to have systemic embolization following lead infection.[32] A recent echocardiographic study on 1,084 patients with device implantation found that out of 32 patients with visualized thrombus on leads, 17 patients had endocarditis.[33]

More recently, a multicenter study by Khairy et al on 202 patients showed that congenital cardiac defect patients who had a transvenous lead had more than 2-fold increase in the risk of thromboembolic event, as compared to patients with an endocardial or no lead.[34] In their study, the higher probability of an embolic event was seen even after adjusting for baseline clinical risk factors, but the significance was lost after adjusting further for important stroke

related factors such as past thromboembolic event, Atrial Fibrillation and other variables. Conversely, a study by De Simone et al. of 6,075 patients with device implantation yielded similar results with PFO patients having a higher rate of stroke/TIA as a future event compared to patients without PFO, even after adjusting for other risk factors (8.2% vs 2.0%; HR 3.36; 95% CI 2.23-5.07; p-values < 0.0001). [35] This study raised important questions about the risk of embolism associated with the device in the presence of PFO. However, in a subsequent study done by the same group with the same cohort, they opined that the increase in risk of stroke/TIA may have an association with PFO itself rather than the device. [36] They studied various characteristics of the device and its possible association with neurological events and found that the tined lead, which anyway is losing prominence and is gradually being replaced by fixated leads, was an independent predictor for stroke in patients with a device. Furthermore, in a similar study including the same cohort, no difference in PE was detected between the patients with device (or device related characteristics) and the age/gender matched general population. Also, it was observed that most of the patients (84%) with PE had other established reasons for the embolic event. [37] Moreover, even the abandoned leads were not found to be associated with thromboembolic complications when patients with abandoned leads were followed for a period of 3 years. [38] Overall, no positive independent association between device and embolic event (stroke or PE) has been confirmed through recent large studies, although none of these studies specifically examined the possibility of a device or its components (and not PFO) as the cause of prospective neurological events.

One recent propensity matched study of 2,921 patients (device versus no device group) specifically scrutinized the possibility of the device as the source of stroke/TIA in PFO patients and found no difference in stroke, TIA or both outcomes between patients.[39] They included medication history, excluded patients with prior neurological events, and accounted for patients who had PFO closure after inclusion in the study. The major limitation was the low event rate which may preclude any significant result between the two groups, but the propensity matching made it as close to a randomized trial as possible with a retrospective study. Nevertheless, this was the largest recent study designed to specifically look into devices as the possible cause for embolism in the patient population.

Table. 1.

Study, Year	Patient Cohort, Number	Exclusion Criteria	Age (years), Male (%)	Relevant Characteristics	Follow-up	Outcomes
Khairy, P. et al, 2006 [34]	Patients with any Intracardiac shunt grouped into transvenous, epicardial and no leads, 202 patients	Patent ductus arteriosus and PFO	26.19±14.06, 96 (47.52)	Documented Right-to-left shunt - 149 (73.53%), Atrial Fibrillation / Flutter – 63 (31.19%)	12.66±15.0 8 years	After multivariate adjustment - point estimate for transvenous lead as independent risk factor for systemic thromboembolic episode (HR: 2.1;95% CI: 0.6 to 7.1; P=0.2274)

Study, Year	Patient Cohort, Number	Exclusion Criteria	Age (years), Male (%)	Relevant Characteristics	Follow-up	Outcomes
Glickson, M. et al., 2009 [38]	78 ICD patients with 101 abandoned leads	-	63±14, 63 (81)	-	3.1±2.0 years	No clinically apparent thromboembolic complications due to abandoned leads
DeSimone, C.V. et al., 2013 [35]	All patients with transvenous implantation of pacemaker / ICD, 6075 patients	Patients lacking details about timing, mechanism, or cause of stroke/TIA (40 patients), unconfirmed PFO (74 patients)	66.87±16.90, 3891 (64.05)	Atrial Fibrillation - 2672 (43.98%), Prior Stroke /TIA - 910 (15%),	4.7±3.1 years	After multivariate adjustment - association between PFO and stroke/TIA in patients with endocardial leads (8.2% vs. 2.0%: HR: 3.30; 95% CI: 2.19–4.96; $P<0.0001$)
Vaidya, V.R. et al., 2014 [36]	All patients with transvenous implantation of pacemaker/ ICD, 5646 patients	Patients lacking details about timing, mechanism, or cause of stroke/TIA	67.3±16.3, 3613 (64)	Atrial Fibrillation - 2535 (45%), Prior Stroke /TIA - 852 (15%)	-	After multivariate analysis - older age, female sex, documented PFO, prior history of stroke/TIA presence of timed leads (HR: 1.41; 95% CI: 1.00–1.97; $p=0.049$) were associated with an increased rate of stroke/TIA
Poddar, K.L. et al., 2014 [39]	All patients with PFO divided into device and no device groups (231 patients in each group, 2921 patients)	Prior Neurological event, PFO closure during follow up (if no event before closure)	76.33±13.75, 271 (58.66)	Atrial Fibrillation - 264 (57.14%)	At least 4 years follow up completed for each patient	Propensity matched analysis - Stroke/TIA outcomes were not different between the two groups (4.3% vs. 5.2%; $P=0.83$)
Noheria, A. et al., 2015 [37]	All patients with transvenous implantation of CIED, 5646 patients	-	67.3±16.3, 3614 (64)	Atrial Fibrillation - 2566 (45%), Prior Stroke/TIA - 849 (15%)	Mean follow up of 4.69 years	No statistical association between PE event and number of leads or type of device
PFO: Patent foramen ovale; ICD; Implantable cardioverter defibrillator; TIA: Transient ischemic event; CIED; Cardiac implantable electronic devices; PE: Pulmonary embolism						

Considering the absence of consensus on definite embolic risk factors and the fact that these studies leaves us with little evidence to independently link a device or its components

with stroke, it can be safely concluded that the risk of thromboembolism in patients and who require a pacemaker or ICD are most likely multifactorial.[40, 41] Therefore we divert our focus to other pertinent and accepted risk factors associated with a subsequent neurological event.

DEVICE AND PATENT FORAMEN OVALE

PFO, a defect due to incomplete fusion of septum primum and septum secundum, is a common benign entity present in around 20-25% of the population and is mostly an incidental finding during echocardiography as part of clinical investigations or during autopsy. The presence of the channel, which allows for paradoxical embolism, generated interest to evaluate the relationship between PFO and stroke. Brogno et al. showed evidence of the passage of thrombus through the PFO [42, 43], even though the probable association of PFO with CS was first reported much earlier in 1988 by Lechat et al.[77] It was later studied by others, where PFO as an independent risk factor of stroke was discussed, but with conflicting evidence.[44-46] Overall, various studies associated PFO with thromboembolism, with many of those showing an association between PFO and CS, suggesting a role for PFO in stroke pathophysiology.[44] A meta-analysis of retrospective studies showed that patients <55 years who sustained a CS had a PFO prevalence 6 times greater than that of patients with other forms of stroke, while Handke et al. showed that the prevalence was higher among patients with CS than among those with stroke of known cause in both younger and older patients, suggesting paradoxical embolism as a cause of stroke [47-51]. These studies suggest that PFO is more common in patients with a CS (approximately 50% to 60% vs. 20% to 25%) or in patients with stroke of determined origin as compared to the general population. In contrast, a recent trial of 909 patients concluded that alternative etiologies, and not PFO, were mostly responsible for stroke/TIA in patients with documented PFO.[52] Furthermore, a recent meta-analysis of the relevant studies (recurrent cerebrovascular events and ischemic stroke or TIA in patients with PFO) from 1999 and beyond, found that patients with PFO and stroke do not have a higher propensity of either stroke or the combined end point of stroke/TIA as compared to patients with PFO (RR 1.18; 95% confidence interval (CI) 0.78–1.79; P 0.43).[53]

Conflicting results are mainly attributed to vastly different and weaknesses in methodologies, use of mainly retrospective and circumstantial evidence and poor control selection. Also, the studies were unadjusted for important co-morbidities and parameters, apart from limitations associated with low outcomes, an inherent limitation considering the event rate, decreasing the possibility of statistical significance. Overall, the relation has oscillated between causal, incidental or even no connection between the two entities in question. More so, considering that PFO is a normal anatomic variant and can exist in one-third of any study population by chance.[44] This makes the studies prone to under recognition of PFO in the comparison group apart from the possibility of selective referral.[54] The role of the investigation methodology may also be very crucial in determining the scope of risk.[53]

Transesophageal echocardiography (TEE) remains the mainstay investigation in patients with PFO as transthoracic echocardiography (TTE) is largely deficient for delineating PFO

and its characteristics when compared to TEE. TEE can be used to find PFO in different ways: finding abnormal flow through use of color doppler, direct B-mode visualization of the separation of the septum primum and septum secundum by omniplane transducer, and also by visualization of movement of injected saline. While TEE has a sensitivity of 89% and specificity of 100% in detecting PFOs compared with autopsy diagnosis, TCD can detect around 90-100% PFOs. TCD has been particularly helpful for visualizing small PFOs mainly because of the possibility of eliciting stronger Valsalva Maneuvers which can be further confirmed by the waveform. In one of the study, It was even advised that TCD be used as the first choice for screening patients with suspected PFO, as they found that in 4.8% of cases, TEE failed to reveal the contrast passage unlike TCD.[55] Even though TEE may sometimes lead to gross underrepresentation of presence of thrombus in patient with device implantation [56], it is still considered the gold standard for visualization in case of suspected emboli or stroke in such patients. The benefit offered by TEE is the additional information it provides apart from the advantage of direct visualization, i.e., atrial details and possible identification of atrial or aortic source of emboli such as ASA.

Various PFO specific parameters were studied to understand the anatomy associated with the stroke risk, but clearly, the 'defect' feature which has received maximum attention is the presence of concomitant atrial septal aneurysm (ASA) [57, 58] and to large extent, the shunt/PFO size, which may, in turn, be co-related to the amount of shunt across the defect.[59] Earlier studies have shown significant positive association of the shunt size with neurological event, or a trend towards it.[58, 60-65] The reason for discrepancies between the findings seems mainly due to the different definitions for the degree of shunting used in these studies. Goel S et al. studied consecutive 102 patients, without prior history of neurological event, and divided the shunts into mild (3 to 9 microbubbles in the left atrium at rest or after valsalva maneuver), moderate (10 to 30 microbubbles) and severe (30 or more microbubbles) categories and co-related it with the size of PFO and found that degree of shunting worsened with increasing PFO size.[59] More recently, in a meta-analysis done on 4251 patients, transcranial doppler ultrasound (TCD) studies suggested an increased risk of stroke/TIA in patients with moderate/severe shunt as compared to patients with small shunt (HR 2.91; 95% CI 1.32 – 6.41; P-Value 0.008).[53]

ASA, a congenital malformation of the atrial septum characterized by the bulging of the septum overlying the fossa ovalis into either atrial chamber, has also been implicated to be, possibly, the only potential cardioembolic source of thrombi (irrespective of presence of PFO) in patients with cerebral ischemia [66], as its thrombus can be observed in the base of aneurysm or as fibrin-thrombus tags on the convex surface of ASA.[67] Its association with PFO is not only shown to be increasingly found along with PFO [68], but also to synergistically increase the chance of embolism while co-occurring with PFO.[50]

Various prospective studies which dealt with the question of increased risk of stroke with both PFO and ASA were ambiguous. While some studies showed the combination as predictor of increased stroke [50, 69], other studies found the association to be insignificant.[69-71] The French PFO/atrial septal aneurysm (ASA) published in 1995 concluded that the combination of ASA and PFO is predictive of higher recurrent stroke risk [72], but the PFO in cryptogenic stroke (PICSS) study published in 2002 did not find any relation of PFO with stroke, with or without ASA.[69] Devuyst G et al. appreciated the difference in mean age between the patients of these two studies and performed a meta-

analysis using this two studies and concluded that it is possible that the association may be influenced by the age group of the patients. [73]

OTHER RISK FACTORS

Age has been found to be an important factor which seems to follow an inverse relation as far as stroke is concerned in PFO population. Meta-analysis by JR Overell et al. clearly shows how age differs across between the 'positive causal' relation against the 'neutral or negative studies'. [51] They divided more than 15 studies from the two mentioned groups and found mean age to be to be significantly different between the two groups, 44.8 years in 'positive causal' studies [57, 74-80] versus 61.1 years in 'neutral or negative' studies [81-87] thus indicating that the embolic event and PFO may be associated in young population, but less so in the older age group. In an analysis between cryptogenic and conventional stroke, more than 2 fold increase in the prevalence of PFO was observed in young population (< 55 years) as compared to older population (≥ 55 years of age). [44] This possibility can be explained by the fact that the prevalence of PFO decreases with the age. [88] Interestingly, the decrease of PFO prevalence with age, coupled with the finding of decreased association of PFO with stroke in the elderly, does substantiates that in the young, PFO may actually not be a silent bystander. But the same can be countered by the fact that as age advances, other thrombotic/embolic risk factors such as atrial fibrillation, atherosclerosis, diabetes and other co-morbidities may actually offset the role of PFO as a causal factor for any embolic event, and thus make PFO less relevant for any neurological event probability.

Apart from age, the other important concurrent pathology with respect to stroke associated with device implantation is arrhythmia, mainly AF, which can act as a precursor for an embolic event. [89] With the help of a gene expression profile study, it was found that nearly 58% of cryptogenic strokes actually have a undetected cardioembolic cause. [90] Many studies confirmed the presence of short lived arrhythmic properties, such as paroxysmal atrial fibrillation, in as much as 20% of cryptogenic stroke patients when patients underwent prolonged monitoring. [91-99] This is apart from findings of EMBRACE and CRYSTAL-AF trials which showed an increase in AF detection with prolonged monitoring. [100, 101] Additional arrhythmias such as paroxysmal atrial flutter [102], paroxysmal supraventricular tachycardia [103-105], sick sinus syndrome [106, 107] and atrial high-rate episodes in patients with cardiac pacemakers [108] also add to the unknown causes of cryptogenic stroke, which constitute a large proportion of stroke population ranging from 20% to as high as 40%. [109, 110] Hence, it is highly likely that cryptogenic stroke attributed or attributable to devices may actually have an undetected arrhythmic origin and thus the possibility of missed arrhythmia in such patients needs to be acknowledged.

Here it is important to note that the term cryptogenic stroke actually encompasses stroke of undetermined origin under various conditions, If the diagnostic assessment of the stroke event is incomplete, or after extensive investigation no cause could be found, or when a cause for stroke is not specified because more than one possible reason is found during investigation. [111] In a comprehensive review published in *LANCET Neurology*, a more specific term, (ESUS) was used to clarify the concept of cryptogenic stroke [112], as is understood in normal clinical practice. According to them, a diagnosis of ESUS should be made after thorough investigation has been done to exclude major risk cardioembolic sources,

occlusive atherosclerosis, and lacunar stroke. It may be beneficial to undertake similar investigation as designed to diagnose embolic stroke of undetermined source when planning a device implantation procedure in high risk patients, or those with prior history of embolic event.

Procoagulant conditions may also have the propensity to impact the management strategy of patients who may be more prone to thrombotic events such as device implantation. Though there are many such factors which can be classified as being prothrombotic, ranging from complex inherited/acquired thrombophilic conditions and antiphospholipid antibody syndrome to more common entities such as malignancy, smoking, OCP use and even female gender.

The association of a hypercoagulable state and stroke had been studied in detail, but studies looking specifically at the risk of clinical stroke/TIA in patients with a hypercoagulable state and subsequent device implantation were not done. Considering the low event outcome coupled with chances of few qualifying patients, such a study seems unlikely, and in its absence, focus may be given to studies dealing with common hypercoagulability status and stroke in PFO patients. Few independent retrospective studies analyzed different prothrombotic markers in patients with cryptogenic stroke and PFO: antiphospholipid antibodies (APS) [113-117], protein C and protein S deficiencies [116, 117], factor V Leiden mutation (FV_{G1691A}) [116, 118-121] and prothrombin gene mutation (PT_{G20210A}) [118, 119, 121], but the studies included either very few numbers of patients or the designs were not robust enough to be considered relevant to be incorporated into clinical practice.[122] Out of the mentioned conditions, the most common entities are heterozygosity for factor V Leiden (FVL) and PT, the two most common genetic risk factors, and also the antiphospholipid antibody syndrome (APS), one of the most important acquired risk factors for thrombosis.

FVL, present in as high as 5% in white Americans is notably the most common prothrombotic genetic predisposition.[123] Meta-analysis in the early 2000s have supported an association between FVL and first ischemic stroke [124-126] but two recent large studies were not able to find any association between FVL and first ischemic stroke and recurrent stroke. [127, 128] As far as PFO patients are concerned, the absence of association is further confirmed through various studies along with meta-analysis done by Pazzini et al.[129, 130] Overall, no conclusive proof was found to positively link FVL with risk of stroke in PFO patients.

Unlike FVL, meta-analyses showed a degree of association (OR 2.31; 95% CI 1.20 – 4.43) of prothrombin mutation with stroke risk in PFO patients, when PFO related stroke patients were compared with non-PFO stroke patients, although the largest study among them on 416 patients [119] apparently showed no association (OR 2.01; 95% CI 0.69 – 5.89). The most recent study published in 2012 by Favaretto et al. consisting of 340 patients, who also underwent TCD, did show association of G20210A mutation with cryptogenic stroke (OR: 2.97; 95% CI: 1.32-6.69) but no association with PFO (OR: 0.88; 95% CI: 0.39–2.01) or the RLS grading as assessed by TCD.[130]

Anti phospholipid syndrome, an acquired autoimmune disorder involving systemic circulation, by far seems to be strongly associated with chance of stroke in patients, with study findings it to be present in around 20% of young patients with thrombophilia.[131, 132] In a large systematic review of 5,217 patients from 43 different studies, the author found a 5-

fold increase in stroke/TIA with presence of aPL.[133] Furthermore, Pezzini et al. showed an association of neurological outcomes with the classical risk factors along with circulating antiphospholipid antibodies (aPL). They found that even after adjusting for other predictors, patients with persistent aPL has around 2 to 3 times higher risk of neurological events.[129] Overall, the literature seems to be consistent with a positive association of aPL with stroke [134-137], along with association between PFO and APS [138]. In contrast to that, Rajamani Kumar et al. provided results from a large study [139] which included patients who had TEE as part of the Patent Foramen Ovale in Cryptogenic Stroke Study (PICSS), and the aPL measurement through phospholipid and Antiphospholipid Antibodies and Stroke Study (APASS) (both studies relying on the Warfarin Aspirin Recurrent Stroke Study (WARSS) trial for patient recruitment). [69, 140, 141] In their analysis of 530 patients, they did not find an association of stroke with concomitant findings of aPL and PFO.

Overall, despite the association of hypercoagulable state with stroke risk in the general population, studies showing an additive or causal relationship of such prothrombotic states with device implantation and a neurological event have been limited to few cases. [142-144] Nevertheless, it is highly plausible that that insertion of an intravenous lead may tilt the balance towards higher risk in this hypercoagulable subset of patients. In lieu of absence of conclusive data, the insertion of an intravenous lead/device may be considered an additive risk factor in presence of a prothrombotic state, more so in the presence of past history of stroke or an associated clinical risk factor. Under such circumstances, the decision should be case specific. When in doubt, further investigation for prothrombotic status and markers should be done to help choose from various medical and interventional options and to form a comprehensive secondary preventive strategy.

MANAGEMENT

The current PACES/HRS Expert Consensus Statement on the Recognition and Management of Arrhythmias in Adult Congenital Heart Disease, endorsed by the governing bodies of PACES, HRS, the American College of Cardiology (ACC), the American Heart Association (AHA), the European Heart Rhythm Association (EHRA), the Canadian Heart Rhythm Society (CHRS), and the International Society for Adult Congenital Heart Disease (ISACHD), classify the placement of endocardial leads in the presence of CHD and intracardiac shunts under class III recommendation with level of evidence B.[145] The recommendation relied on advice from the earlier Canadian consensus statement of 2008 and ACC/AHA guidelines published in 2008.[146, 147] While the Canadian Consensus statement recommends avoiding transvenous pacing in patients with unrepaired ASD (level of evidence C), the ACC/AHA consensus statement advocated use of an epicardial pacemaker in patients with intracardiac shunt (Level of evidence B). This points to that fact that in the last few years either the evidence in favor of using device placement in patients with CHD are few or are conflicting in nature. Until further data are published or randomized trials are done, it is recommended to tread with caution, and it may be beneficial to thoroughly investigate each patient to look for pro-thrombotic/embolic risk factors and direct the management accordingly.

Medical management of patients undergoing device implantation largely depends upon their thromboembolic risk. In patients considered high thromboembolic risk and on oral anticoagulation (OAC) therapy, suspension of OAC treatment in lieu of 'bridging' heparin during the procedure was the norm, despite various studies finding no increased risk of bleeding with continued use of warfarin during the procedure.[148-152] Ghanbari Hamid et al. did a meta-analysis using available studies and concluded against use of heparin 'bridging' during the implantation procedure.[153] In 2013, a randomized trial confirmed the results as they found significant reduction in clinically significant hematoma in the warfarin group, as compared to the heparin 'bridge' group.[154] Pending further evidence, continuing with warfarin (anti-coagulant) seems to be the preferred option, even though individual thromboembolic risk assessment may provide additional information to direct intra- and post-procedural management.

The other important role of medical or interventional management deals with patients with suspected or confirmed PFO who are undergoing device implantation, as PFO is widely considered an additional risk factor in patients undergoing device implantation. Different medical management strategies have been studied with respect to this patient population with use anti-platelets or anti-coagulants. The two major studies (Patent Foramen Ovale in Cryptogenic Stroke Study (PICSS) and Spanish Multicenter Study (CODICIA)) concerning the use of medications in these patients found similar stroke recurrence rates among various patient groups. No difference was found in outcome rates between all patients taking aspirin or warfarin (2-year event rates 14.8% versus 15.4%; hazard ratio 0.96; P 0.84; 95% CI 0.62 to 1.48) and also in the cryptogenic stroke subset of patients (2-year event rates 14.3% versus 12.7%; hazard ratio 1.17; 95% CI 0.60 to 2.37; P 0.65). Similarly no difference in outcome was observed between patients with massive, non-massive and no right-to-left shunt (3.4% vs 2.3% vs 4.5%, respectively; p 0.75). Similar results were obtained in patients with PFO and ASA as compared to those with ASA alone and across younger and the overall population.[69, 155] Generally, it can be concluded that in most of the studies significant benefit of one medical treatment over the other does not exist.

At present guidelines suggest use of anti-platelets for patients with ischemic stroke in the absence of an identified embolic source.[156] Until the results of 'RE-ESPECT-ESUS' trials provide further evidence it may be beneficial to use anti-coagulants in patients who have PFO and identified cases of embolic strokes of undetermined sources along.[112, 157] As for AF, recent guidelines recommend use of CHA2DS2-VASc for risk stratification for the possibility of stroke occurrence.[158] Other risk scoring system, namely CHADS₂ score [159], the Anticoagulation and Risk Factors in Atrial Fibrillation (ATRIA) stroke score [160], the Qstroke score [161] are also studied, but CHA2DS2 risk score remains the most widely used and recommended score system to stratify AF patients for optimal therapy. Overall, the medical management in these patients should be best advised keeping in mind the associated clinical features such as thrombogenic potential of concomitant risk factors such as atrial fibrillation, other co-morbid conditions and risk of bleeding, and other adverse complications associated with the use of anti-coagulant or anti-platelet use.[162]

Device closure of PFO got overt attention in recent times with the introduction of closure devices, i.e., Amplatzer PFO occluder (St. Jude Medical), STARflex and others. It was presumed that device closure of PFO may be advantageous to groups of patients undergoing device implantation, as PFO is invariably present in a large number of patients undergoing implantation, and its closure may help to block the conduit of emboli through the defect.

Backed by the studies that showed probable benefits of closing the PFO, it was speculated that closure of a defect may be beneficial, especially in cases of cryptogenic stroke, with introduction of the closure devices. Though all three recent major trials comparing outcomes of closure devices with medical therapy [163-165] failed to show significant benefits with closure of defects, all of them were consistent with regards to patients in medical management groups experiencing a higher number of events. Also the events per patient year were consistently higher with medical therapy, but the quantitative (not statistical) benefit, to an extent, is being offset by the higher number of new onset atrial fibrillation cases.[166]

When the stratified analysis of the two trials using the Amplatzer PFO Occluder device was performed, the results favored the use of the device as compared to medical management, but only with respect to stroke (HR 0.44; 95% CI 0.20 – 0.9; P-value 0.04) and not TIA (HR 0.8; 95% CI 0.37 – 1.74; P-value 0.58). This result seems to be consistent with the pooled analysis of data from 11 observational studies by Capodanno D et al.[167] The RESPECT trial did show significantly better outcomes with respect to stroke in the ‘as-treated’ cohort (HR 0.27; 95% CI 0.10 – 0.75; P-value 0.007), which in turn seems to be influenced by better performances in the substantial shunt size (HR 0.18; 95% CI 0.04 – 0.81; P-value 0.01) and atrial septal aneurysm (HR 0.19; 95% CI 0.04 – 0.87; P-value 0.02) sub-groups.[163] Meta-analysis done by Agarwal S et al. [168], showed the rate of recurrent neurological events to be as high as 5 events per 100 patient years (95% CI: 3.6 to 6.9) in the medical management groups as compared to 0.8 (95% CI: 0.5 to 1.1) in the closure group, and the analysis revealed that elderly patients, patients with concomitant ASA and thrombophilia benefitted the most with device closure.

Despite the absence of statistical benefit in overall cohort in the randomized trial, these findings suggest that closure of PFO in patients with higher risk such as ASA or shunt size may be beneficial with respect to stroke risk. It remains to be seen whether benefit increases or reduces with a longer follow up period. Even though device closure is a promising alternative, presently, it can be potentially only used for patients who have a very high likelihood of an embolic event. Insertion of devices such as pacemaker or ICD may seem to add to the risk of thromboembolic event, but prophylactic closure of PFO solely based on risk offered by intravenous device placement does not seem to offer any significant clinical benefit and is not recommended. These necessitate further studies centered on a specific patient population and longer follow up to find the patients who may benefit from the closure therapy. Furthermore, the value and usefulness of closure devices needs to be further ascertained before considering it as a viable alternative to the present medical management for patients at moderate or low risk, including those undergoing intravenous device implantation.

With respect to newer developments in this field, the introduction of a leadless pacemaker seems to bring a significant paradigm shift in the technology. Even though new developments are still undergoing and the short- and long-term results of this device have been satisfactory [169, 170], it remains to be seen whether leadless pacemakers may act as a nidus for any thrombogenic and subsequent embolic activity. In the absence of an intravenous component, the possibility is rare. Hopefully, it would give rest to the issues of stroke or thromboembolic events in patients undergoing device implantation.

CONCLUSION

Data associating risk of stroke in patients undergoing device implantation are mostly non-confirmatory, and independently associating devices (leads) with stroke/PE may be an overestimation. In the absence of definitive data, emphasis should be given to careful and thorough evaluation of underlying thrombotic/embolic risk factors for patients undergoing device implantation. It is highly plausible that the risk of thrombus formation followed by embolism is essentially multifactorial in origin, wherein two or more factors combine or work synergistically to increase the probability of future adverse events. This seems more likely, because even though numerous studies have attempted to find independent predictors, they have resulted in diverse outcomes. This further points to the importance of extensive investigation to rule out various causes of cryptogenic stroke or embolic stroke of uncertain origin. Different medical management studies have been inconclusive, while interventional PFO closure as the strategy to prevent future embolic events was not found to be superior to medical management in the overall population, even though it is possible that selected high risk patients may benefit from closure. Intravenous device placement alone does not justify closure of PFO to decrease embolic risk. Managing patients by risk stratification based on identified risk factor of stroke may be the best way until further evidence is obtained. Further, long term prospective studies may add valuable information for clinicians. As for stroke/thromboembolism risks, leadless pacemakers may prove to be beneficial for patients requiring device implantation.

1. OVERVIEWS

Liyan Qiao

Stroke is identified by the sudden occurrence of a nonconvulsive, focal neurologic deficit. The classic etiologies of the stroke are: thrombosis, embolism, and hemorrhage. The major types of stroke include: atherosclerotic thrombosis, lacunes, embolism, hypertensive hemorrhage, ruptured aneurysms and vascular malformations, among others (Victor and Ropper, 2001)

Among all the neurologic diseases of adult life, stroke ranks first in frequency and impact on disability. Stroke constitutes at least 50 percent of the neurologic disorders in a general hospital. Stroke, after ischemic heart disease, is the second-commonest single cause of death worldwide, with over 5 million deaths per year globally. Despite advances in acute care and secondary preventive strategies, stroke remains a major burden on health-care resources worldwide. Conventional therapeutic measures have failed to restore neurological function post stroke. However, cell-based neurorestorative strategy is an emerging therapeutic modality and there is evidence that this therapy provides therapeutic benefit for the treatment of stroke.

1.1. Incidence

U.S. Census Bureau has forecasted the distribution of incident stroke cases for the years 2010 to 2050. Over these 40 years, the number of incident strokes is expected to more than double, with the majority of the increase among the elderly (age >75 years) and minority groups (particularly Hispanics) (Howard G and Goff DC, 2012).

1.2. Risk factors

Several factors are known to increase the likelihood of stroke. The most important of these are hypertension, heart disease, atrial fibrillation, diabetes mellitus, cigarette smoking, and hyperlipidemia. Others, such as systemic disease associated with a hyper coagulable state and the use of birth control pills, also contribute, but to a lesser degree (Victor and Ropper, 2001).

1.3. Pathophysiology

Cerebral infarction basically comprises two pathophysiologic processes, 1) a loss in the supply of oxygen and glucose secondary to vascular occlusions and, 2) an array of changes in cellular metabolism as a consequence of the collapse of energy-producing processes, with damage to cell membranes. Of potential therapeutic importance are the observations that some of the cellular processes leading to neuronal death are not irrevocable and may be reversed by early intervention, either restoration of blood flow or prevention of the influx of calcium into the cell (Victor and Ropper, 2001). In cerebral hemorrhage, the resulting hematoma within brain parenchyma triggers a series of adverse events causing secondary insults and severe neurological deficits. The pathological pathway of second injury includes cytotoxicity of blood, hypermetabolism, excitotoxicity, oxidative stress and inflammation (Aronowski and Zhao, 2011).

1.4. Treatment

1.4.1. Management of Acute Phase of Intracerebral Haemorrhage

Hemorrhagic strokes are relatively less common compared to ischemic strokes, with the vast majority of hemorrhages being intracerebral as opposed to subarachnoid. The definitive diagnosis of a hemorrhagic stroke is based on CT imaging of the brain. Acute care should focus on prompt identification of the cause of haemorrhage, minimizing the risk of hemorrhage expansion by controlling blood pressure and correcting any underlying coagulopathy, and obliterating vascular lesions with a high risk of rebleeding (Flower and Smith, 2011).

1.4.2. Management of Acute Phase of Ischaemic Stroke

Thrombolysis with tissue plasminogen activator is now a well-established treatment for acute ischemic stroke and is associated with significant improvements in outcomes. Tissue plasminogen activators (recombinant t-PA and streptokinase), when administered intravenously, convert plasminogen to plasmin, the latter being a proteolytic enzyme capable of hydrolyzing fibrin, fibrinogen, and other clotting proteins. The benefits of intravenous thrombolysis up to 4.5 hours are now firmly established. Intra-arterial thrombolysis has been used for decades but data on its efficacy and safety are limited. Novel methods of reperfusion, such as mechanical clot retrieval and stenting, have high recanalization rates with acceptable safety and may be considered in patients with mid- to large-sized artery occlusion (Livesay S, 2014; Kirkman M et al., 2014).

1.4.3. Secondary Prevention

Anti-Platelet Treatment

Due to the high rate of recurrence, in high risk-patients (e.g., patients affected by atherosclerotic vascular disease), long-term antiplatelet therapy has contributed to the significant decline in vascular event rates in patients with ischemic stroke or transient ischemic attack (Hong K, 2014). Current guidelines for prevention of secondary stroke recommend the broad use of antiplatelet therapy for patients with a history of non-cardioembolic stroke or TIA. As for primary prevention, indications are less accurate because the absolute benefits of aspirin in reducing the occurrence of vascular events are generally much lower than in secondary prevention (Pinto A et al., 2014). The common anti-platelet agents include aspirin, clopidogrel, prasugrel and ticagrelor.

Blood-Pressure-Lowering Treatment

High blood pressure in the acute cerebrovascular event is associated with poor outcome. Gradual, sustained lowering of blood pressure is recommended in all stroke patients, but care is needed, particularly in patients with carotid or vertebrobasilar occlusive disease. The ideal time to initiate lowering of blood pressure after stroke is uncertain, but it should be initiated prior to discharge from the hospital. The optimum blood pressure-lowering drugs depend on patient comorbidities. The combination of an angiotensin-converting enzyme inhibitor (or angiotensin II receptor antagonist) and calcium channel blocker (or diuretic in the elderly) may be preferable, because the latter drugs (ie, calcium channel blockers and diuretics) also reduce blood pressure variability. (Hankey GJ, 2014).

Statin Treatment

Statins is now recommended in secondary prevention after stroke or transient ischemic attacks to reduce the risk of a new stroke or major cardiovascular events. However, some issues about the extent of the benefit of statins in some stroke patients and the risk of cerebral hemorrhage remain uncertain (Ní Chróinín D et al., 2013). Statins are effective in decreasing the risk of secondary strokes despite an increase in the risk of brain hemorrhage. A significant benefit of statin therapy was observed in men and women, in aged patients, and possibly in patients with carotid artery stenosis. Intensive statin therapy lowering the LDL-cholesterol beyond the cut-off value of 1.8 mmol/L (70 mg/dl) seems to be more effective than less

intensive treatment and without an increased risk of side effects. Overall, statins are well tolerated (Laloux P, 2014).

Anticoagulant Treatment

In patients with nonvalvular atrial fibrillation, oral anticoagulation with the vitamin K antagonists acenocoumarol, phenprocoumon and warfarin reduces the risk of stroke by more than 50%, whereas single or double antiplatelet therapy is much less effective and sometimes associated with a similar bleeding risk as vitamin K antagonists (Mani and Lindhoff-Last, 2014). Besides bleeding, and intracranial haemorrhage in particular, INR (international normalization ratio) monitoring remains the largest drawback of vitamin K antagonists. In the last decade, oral agents have been developed that directly block the activity of thrombin (factor IIa), as well as drugs that directly inhibit activated factor X (Xa), which is the first compound in the final common pathway to the activation of thrombin. These agents have been approved for stroke prevention in atrial fibrillation patients. Advantages include, no need to monitor. These agents have a fast onset of action, but lack an established specific antidote (Verheugt FW, 2013).

Carotid Revascularization

Patients with recently symptomatic carotid territory transient ischaemic attack or non-disabling ischaemic stroke and ipsilateral 50–99% internal carotid artery stenosis (measured by two concordant non-invasive imaging modalities) who are fit and willing for surgery should be offered carotid endarterectomy as soon as possible, ideally within the first few days and up to 1 week after the ischaemic event and when the patient is clinically stable (Rerkasem K and Rothwell PM, 2011).

Carotid endarterectomy should be done by a surgeon with an audited perioperative morbidity and mortality of less than 5% (Bonati LH et al., 2012).

Carotid endarterectomy is more appropriate than carotid stenting for patients older than 70 years of age who are otherwise fit for surgery because stenting carries a higher short-term risk of stroke and death. Carotid stenting may be as safe as endarterectomy in patients less than 70 years of age.

Carotid stenting could also be considered for patients who are not candidates for carotid endarterectomy because of technical, anatomical, or medical reasons. Interventionists should have expertise in carotid procedures and an expected risk of periprocedural morbidity and mortality of less than 5% (Bonati LH et al., 2011).

2. PRECLINICAL NEURORESTORATIVE STUDIES

Liyan Qiao

2.1. Animal Model

2.1.1. Ischemic Animal Model

Models Requiring Craniotomy

This group of methods requires opening of the skull to allow direct access to the cerebral arteries. In most instances, this has involved small craniotomies that allow distal branches of

vessels such as the middle cerebral artery (MCA) to be ligated, clipped, or sealed by photothrombosis or electrocoagulation (Howells D et al., 2010). Although occlusion of the vessel is usually permanent, ligatures can be released, pneumatic cuffs deflated and even thrombotic lesions created by electrocoagulation or photothrombosis can recanalize to permit transient occlusion.

Models Not Requiring Craniotomy

This group of methods is to use intra-arterial access to occlude cerebral arteries, including embolic model, intraluminal suture middle cerebral artery occlusion (MCAO) model, photothrombosis model, and endothelin-1-induced stroke model et al. Among these models, MCAO is the most commonly used model in the investigation of stroke in rodents (Liu F et al., 2011). This model offers a simple and less traumatic surgical approach, lends itself more readily to the study of reperfusion and has been adapted for use in continuous magnetic resonance imaging, produces focal occlusion of a large cerebral artery as seen in human stroke, and can be done in a high-throughput manner.

Below is an example of MCAO model for rats (Zhang L, 2011). Animals were anesthetized with 3.5% isoflurane and maintained with 1.0% to 2.0% isoflurane in 70% N₂O and 30% O₂ using a face mask. Rectal temperature was maintained at 37°C throughout the surgical procedure using a feedback-regulated water heating system. The right common carotid artery, external carotid artery, and internal carotid artery were exposed. A 4-0 monofilament nylon suture (18.5 to 19.5 mm), determined by the animal weight, with its tip rounded by heating near a flame, was advanced from the external carotid artery into the lumen of the internal carotid artery until it blocked the origin of the MCA. Two hours after MCAO, animals were reanesthetized with isoflurane and reperfusion was achieved by withdrawal of the suture until the tip cleared the lumen of the internal carotid artery.

2.1.2. Intracerebral Hemorrhage (ICH) Model

Three major ICH models have been developed: (1) single blood injection, (2) microballoon-induced formation of ICH, (3) collagenase injection.

Single blood injection commonly involves the intracerebral injection of autologous blood, which is a straightforward and effective technique for producing ICH model. This type of model has been developed in large animals (e.g., dogs, cats, pigs and monkeys), by injecting blood into the frontal lobe. For small animals (e.g., rats and mice) blood is injected into the caudate. This method does not reproduce the arterial vessel rupture present in human spontaneous ICH, but it does control the volume of blood injected and has been shown to be useful for the study of pathophysiological and biochemical consequences of ICH.

Micro balloon insertion was developed as a way to study the mass effects of ICH. A micro balloon was mounted on a no. 25 blunted needle and inserted stereotactically into the right caudate nucleus. The burr hole was then sealed with dental cement. After a 30-min stabilization period, the balloon was inflated to 50 µl over a period of 20 s with radiopaque contrast medium. In the sham-treated control group, the balloon was inserted but not inflated. Brain edema formation was successfully produced, much as occurs in the presence of any intracerebral mass, but the potentially significant effects of the presence of blood and clot in ICH cannot be addressed by this method (Manaenko A, 2011).

Collagenase injection model of ICH involves the injection of bacterial collagenase into brain. Originally developed in rats, this approach has also been used extensively in mice.

Collagenase dissolves the extracellular matrix, ultimately leading to blood vessel rupture and ICH. This model mimics the vascular disruption in spontaneous human ICH, but also induces widespread disruption of the extracellular matrix which is not found in spontaneous cases of human ICH (Manaenko A, 2011).

Below is an example of the ICH mouse model induced by injecting collagenase into the striatum (Xi G et al., 2013). Mice were anesthetized with isoflurane (1.8%) and placed in a stereotaxic frame. A burr hole was made and a 30-gauge needle was inserted into the striatum (location 2.5mm lateral to the midline, 0mm to bregma, 3.5 mm depth below the skull). Half a microliter of saline containing 0.06 IU of collagenase was injected over 5 min using a micropump. After infusion, the needle was left in place for 25min, and slowly removed; the skin incision was sutured. Rectal temperature was maintained at 37.5°C with a heating pad during the surgery. Mice were kept in an incubator to maintain body temperature for 3h after the surgery.

2.2. Neurorestorative Strategies

2.2.1. Medicine and Factors

Following cerebral ischemia, a complicated cascade of biochemical events occurs, ultimately leading to the death of neurons. Within this cascade, many molecular targets can be pharmacologically modulated to produce neuroprotection. The potential targets include glutamate release, glutamate receptor activation, excitotoxicity, calcium influx into cells, mitochondrial dysfunction, activation of many intracellular enzymes, free radical production, nitric oxide production, apoptosis, and inflammation, among others.

Heat Shock Protein (Hsp70)

Preliminary treatment with Hsp70 significantly reduced the ischemic zone. Long-term treatment of the ischemic rats with Hsp70 formulated in alginate granules with retarded release of protein further reduced the infarct volume in the brain as well as apoptotic area. The members of the HSP70 family work together as networks to facilitate organelle communication and regulate inflammatory signaling and cell survival after cerebral ischemia (Shevtsov M et al., 2014).

Estrogens

The potency and efficacy of estrogens for the treatments of ischemia and reperfusion injury, have been well demonstrated for a variety of cell types in the neurovascular unit (Koellhoffer and McCullough, 2013). The effects of estrogens on cerebral vasculature homeostasis and endothelium may reduce disruption of the blood brain barrier (BBB) induced by ischemic stroke (Liu and Yang, 2013).

Voltage-Gated Cation Channel Modulators

One approach to provide therapeutic benefit following ischemic stroke has been to target neuronal voltage-gated cation channels, and particularly blockers of calcium and sodium channels, for post-stroke neuroprotection (Gribkoff and Winquist, 2005). Large-conductance calcium- and voltage-dependent potassium channels (maxi-K channels), which hyperpolarize

ischaemic neurons, reduce excitatory amino acid release, and reduce ischaemic calcium entry (Gribkoff and Winquist, 2005).

NMDA Antagonists

N-Methyl-D-aspartate (NMDA) antagonists which have been investigated in stroke include: aptiganel hydrochloride, dextrophan, dextromethorphan, and magnesium ion (Ogden and Traynelis, 2011). Selective NMDA antagonists such as ifenprodil and eliprodil have demonstrated preclinical neuroprotective efficacy (Kalia L et al., 2008). However, recent findings of a persistent post-stroke decline in NMDA receptor density, which plays a pivotal role in plasticity and memory formation, suggest that NMDA receptor stimulation, rather than inhibition, may prove beneficial in the subacute period after stroke. The beneficial role for NMDA receptor stimulation during the recovery period after stroke is most likely due to enhanced neuroplasticity rather than neuroprotection (Dhawan J et al., 2011).

Radical Scavengers

Radical scavengers (such as vitamin E, sulfhydryl compounds and nitron spin traps) have been studied in stroke, which can promote detoxification of ROS (superoxide dismutase, catalase or peroxidase conjugates), and prevent radical generation. The use of NXY-059 has been associated with clinical benefits in animal models of stroke, and was associated with a significant improvement in the functional recovery (Green and Ashwood, 2005).

Ebselen was shown to attenuate oxidative DNA damage and enhances its repair activity in the thalamus after focal cortical infarction in hypertensive rats (He M et al., 2007). A subsequent study has shown that Ebselen provided protection against delayed neuronal death and oxidative damage from focal ischemia in hypertensive rats when administered 24 h post-stroke (Rawan and James, 2010).

Wu et al., (2014) systematically reviewed the efficacy of edaravone in animal models of focal ischemia. They identified 49 experiments describing edaravone outcome in 814 animals; 30 experiments (519 animals) reported functional benefit and 35 experiments (503 animals) reported improvement in structural outcome. Edaravone improved functional and structural outcome by 30% (95% confidence interval 23-37%) and 25% (95% confidence interval, 21-29%), respectively.

Statins

Continuous oral administration (avoiding withdrawal) with statins after stroke may reduce the extent of post-ischemic brain damage and improve neurological outcome in rats (Saito T, 2014).

2.2.2. Bioengineering

Stimulation of cerebral angiogenesis by gene delivery is under extensive investigation. (Kurinami H et al., 2014). Vascular endothelial growth factor (VEGF) enhances neurogenesis in ischemic brains. Li et al., (2009) transferred the VEGF gene into brain tissue with recombinant adeno-associated virus serotype 1 (rAAV1) vectors and VEGF expression reduced the size of cerebral infarction and improved neurological function. It also enhanced the proliferation of neural progenitor cells in the subventricular zone and promoted their migration to the ischemic lesion. Neural precursors in the subgranular zone of the dentate

gyrus were also increased; however, most of these cells did not move to the ischemic lesion and integrated within their region of origin.

Endothelial cell proliferation and the number of newly formed microvessels were greatly increased in the MicroRNA-210 (miR-210)-mice (Zeng L et al., 2014).

Gene-Modified Stem Cells

Keeney et al. (2013) described a recently developed strategy for stimulating vascular growth by programming stem cells to overexpress angiogenic factors in situ using biodegradable polymeric nanoparticles. The strategy utilized stem cells as delivery vehicles by taking advantage of their ability to migrate toward ischemic tissues in vivo. Using the optimized polymeric vectors, adipose-derived stromal cells were modified to overexpress an angiogenic gene encoding VEGF in a mice hindlimb ischemia model. Prior to Keeney's work, Cho et al. (Cho et al., 2012) developed nanoparticles as vehicles to genetically modify human umbilical vein endothelial cells with VEGF. In a mouse model of hindlimb ischemia, VEGF nanoparticle transfection promoted engraftment of umbilical vein endothelial cells into mouse vasculature as well as survival of transplanted cells in ischemic tissues.

Bone marrow mesenchymal stromal cells transfected with a vector encoding human Notch1 intracellular domain was shown to be effective for the treatment of a chronic stroke model, exhibiting equal or superior immunosuppressive and angiogenic activity to parental MSC in vitro, and producing extracellular matrix that is exceptionally supportive for neural cell growth (Aizman et al., 2014).

2.2.3. Cell Therapy

Granulocyte-Colony Stimulating Factor (G-CSF)

Broadly speaking, clinical cell-based neurorestorative therapy can be divided into "endogenous" and "exogenous" approaches: The endogenous approach aims to stimulate mobilization of stem/progenitor cells already present within the individual. G-CSF is one of the successful examples for endogenous approaches. G-CSF is used to mobilize hematopoietic stem cells into the peripheral blood.

However, G-CSF has also been shown to have neuroprotective properties beyond simply cell mobilization, and reduces infarct volume in experimental cerebral ischemia (England T, et al. 2009). In the acute phase of cerebral ischemia, the neuroprotective mechanism of G-CSF includes inhibition of glutamate release, reduction of inflammation, antiapoptotic activity, and suppression of edema formation (Nomani F et al., 2013). Further, G-CSF has a direct protective effect against glutamate-induced excitotoxicity in cultured neurons (Pan C et al., 2010).

Embryonic Stem Cells (ESCs)

Daadi et al. (2009) transplanted NSPCs derived from ESCs into the post stroke rat brain, and showed that transplanted cells could differentiate into neurons, oligodendrocytes, and astrocytes. Neural progenitor cells derived from murine or monkey ESCs were also reported to survive in stroke lesions of brain, and differentiated into mature neurons (Buhnenmann et al., 2006; Hayashi et al., 2006).

These results indicate that ESCs are a promising cell source, but human fertilized eggs are needed to establish each ESCs. This ethical problem interferes with the clinical application of ESCs. Risk of tumorigenesis is a major obstacle to human embryonic and induced pluripotent stem cell therapy (Seminatore C et al., 2010).

Induced Pluripotent Stem Cells (iPSCs)

Many researchers have reported that hiPS cells could be differentiated into various kinds of neurons including glutaminergic (Qiang et al., 2011), motor (Ebert et al., 2009), and dopaminergic (Caiazzo et al., 2011) neurons. After human neural precursor cells (hNPCs) derived from iPS cells were transplanted into the murine brain they survives as mature neurons (Chen et al., 2010).

It has been shown that grafted human iPSCs survive, differentiate to neurons and ameliorate functional deficits in ischemic stroke aged brain (Tatarishvili J et al., 2014; Yuan T et al., 2013; Chen SJ et al., 2010). In addition, human skin-derived iPSCs can be specifically differentiated into cortical neuronal progenitors, which survive, differentiate to functional neurons and improve neurological outcome after intracortical implantation in a rat stroke model (Tornerio D et al., 2013). Transplantation of iPSCs also contributes the improvement of neurological function in experimental intracerebral hemorrhage rats (Qin J et al., 2013). iPSC-derived NPCs are effective cells for the treatment of stroke. The transplanted animals exhibited significant reduction of stroke-induced inflammatory response, gliosis and apoptosis, and increased endogenous neurogenesis (Chang D et al., 2013; Polentes J et al., 2012). iPSCs have ability to form new functional neurons which accompany functional recovery after stroke (Oki K et al., 2012).

Recently, the creation of vector-free and transgene-free human iPSCs provides a new generation of stem cells with a reduced risk of tumor formation that was associated with the random integration of viral vectors seen with previous techniques. The new kind of iPSCs has been shown to be safe and efficacious in enhancing recovery after focal ischemic stroke in mice (Mohamad O et al., 2013).

Neural Stem /Progenitor Cells (NSPCs)

NSPCs could survive and migrate towards the lesion in rats with an ischemic stroke following intracisternal administration. Electron microscopy examination also suggested that the transplanted cells showed signs of neuronal differentiation (Zhang ZG et al., 2003).

Immortalized Cell Lines: NT2 Cell Line

The immortalized cell line NTera-2 (NT2) was derived from a human teratocarcinoma over 20 years ago (Arsenijevic Y et al., 2001) After several weeks of exposure to retinoic acid and mitotic inhibitors, these cells differentiate into post-mitotic neuron-like cells, named NT2N cells which display a variety of neuronal features (Andrews PW et al., 1984). These cells maintain their neuronal phenotype both in vitro and in vivo for over a year, without reverting to a neoplastic state (Pleasure SJ et al., 1993).

The transplantation of NT2N cells into the ipsilateral striatum of ischemic rat brains could improve functional recovery, with some parameters of behavioral improvement persisting for up to 6 months post-transplantation. Moreover, no evidence of tumorigenicity was found following post-mortem examination of the rats (Banerjee S, 2011).

Mesenchymal Stromal Cells (MSCs)

Transplanted MSCs aggressively can migrate toward the damaged CNS tissue, promote the recovery of motor function after cerebral infarct, rescue the host neurons (Kuroda et al., 2011; Uccelli et al., 2008) and ameliorate neuronal injury (Hokari et al., 2008). MSCs also improve cognitive function due to chronic cerebral ischemia (Shichinohe et al., 2010). To evaluate the quality of preclinical evidence for MSC treatment of ischemic stroke, a meta-analysis showed that 44 /46 studies reported that MSCs significantly improved outcome (Vu et al., 2014).

Umbilical Cord Blood Cells (UCBCs) and Related Cells

Nonfractionated human umbilical cord blood (UCB) (Vandrome et al., 2004) or mononuclear UCB cell fraction (Boltze et al., 2012), have been employed to treat experimental stroke in the laboratory, evoking significant behavioral and anatomical recovery after transplantation. Intraventricular transplantation of UCB-derived mesenchymal stromal cells also significantly attenuated posthemorrhagic hydrocephalus and brain injury after intraventricular hemorrhage (Ahn S et al., 2013).

Iskander et al. using MRI, showed that after intravenous administration of hUCB -derived endothelial progenitor cells in acute rat stroke model, these administered cells accumulated in stroke-affected hemispheres and reduced the infarcted volume (Iskander et al., 2013); however, in another study, most administered cells were found to traffic to the lungs immediately following IV administration and approximately 1% of total administered dose locate at the site of injury (Arbab et al., 2012).

A single injection may be sufficient for effective treatment of stroke with umbilical cord cells. And multiple injections were not superior to single injection therapy in both functional outcome and histological assessments in a stroke model (Shehadah et al., 2013). However, a dose dependent relationship has been shown between therapeutic effect and human umbilical tissue cell number (Seghatoleslam et al., 2013).

Zhang et al. (2013) investigated the effect of UCB cells on aged rats after embolic stroke. Intravenous administration of UCB cells significantly improved neurological functional recovery, increased synaptogenesis and vessel density in the ischemic boundary zone, increased progenitor cell proliferation in the subventricular zone without reducing infarct volume in aged rats.

The same group (Zhang et al., 2012) also tested the efficacy of different administer route, including intraarterial (IA), intravenous (IV), intra-cisterna magna (ICM), lumbar intrathecal (IT), or intracerebral injection (IC).

While IA administration resulted in the highest donor cell number detected within the ischemic brain compared to the other routes, umbilical tissue cells treatments via all routes can provide therapeutic benefit after stroke.

IA, IV, IC seem to bring enhanced benefits due to their ability to increase synaptophysin immunoreactivity and to reduce in apoptotic cells. Transplantation of cryopreserved UCB mononuclear cells does not induce sustained recovery after experimental stroke in spontaneously hypertensive rats (Weise et al., 2014).

3. CLINICAL NEURORESTORATIVE STUDIES

Liyan Qiao, Lin Chen, Hongyun Huang

3.1. Scoring System of Assessment for Stroke

Stroke scales can be classified as clinicometric scales and functional impairment, handicap scales. The severity of the stroke can be assessed by scoring system, such as the National Institutes of Health Stroke Scale (NIHSS) (Brott T, 1989). Despite advantages of modified NIHSS and Scandinavian Stroke Scale comparing to the NIHSS, including their simplification and less inter-rater variability; most of the stroke neurologists around the world continue using the NIHSS (Ghandehari K, 2013). The modified Rankin scale (mRS) and Barthel index (BI) are widely used as functional impairment and disability scales.

3.2. Neurorestorative Strategies

3.2.1. Medicines and Molecules

Many of treatments have been shown to provide neuroprotection in pre-clinical studies. However, this success in the laboratory has not been translated to the clinic, and currently there are no approved neuroprotective or neurorestorative treatments for stroke.

Radical Scavengers

Ebselen has shown some therapeutic promise in patients with acute ischemic stroke in an initial clinical study (Ogawa A et al., 1999). Edaravone has also shown promise in some clinical trials for ischemic stroke. Ishibashi (Ishibashi A et al., 2013) et al. investigated the effect of the administration of edaravone at the acute stage of ischemic stroke. Of the 625 patients enrolled in the study, 237 (37.0%) received both edaravone and conventional treatment, while the other 388 (62.0%) patients underwent conventional treatment only. The administration of edaravone did not have a significant effect on total death from all types of cerebral infarction. However, treatment with edaravone showed a favorable tendency compared to conventional treatment after adjustments for age and gender. Edaravone has been used in patients with acute ischemic stroke in Japan for over 10 years but does not have marketing authorization in Europe or America (Wu S et al., 2014).

Calcium Antagonists

In a meta-analysis of calcium antagonists for acute ischemic stroke, 34 trials were included. No evidence is available demonstrating that calcium antagonists in patients with acute ischemic stroke are effective. In addition, comparisons of different doses of nimodipine suggested that the highest doses were associated with worse outcome (Zhang J, 2012).

NMDA Antagonists

The use of NMDA antagonists was associated with side effects and no clear clinical benefit in clinical trials (Muir K, 2006). Two preliminary trials of intravenous magnesium

show no evidence of adverse effects. In a Phase 2 trial of Selfotel in acute stroke patients, a dose-dependent toxicity was reported (Grotta J et al., 1995).

Scavenging Divalent Metal Ions

DP-b99 seemed well tolerated by patients with acute stroke, and a Phase IIb trial reported better outcomes among DP-b99-treated patients than a control group on a secondary outcome measure (Rosenberg G et al., 2011). However, in a randomized, double-blind, placebo-controlled, multicenter, parallel-group trial of intravenous DP-b99 administered in ischemic stroke patients, DP-b99 shows no evidence of efficacy in treating acute human ischemic stroke (Lees KR et al., 2013).

Minocycline

Minocycline, in small randomized controlled human trials, is a promising neuroprotective agent in acute stroke. However, a large study has not been powered to reliably identify or to exclude a modest but clinically important treatment effect of minocycline (Kohler E, 2013).

3.2.2. Cell Therapy

Cell therapy clinical trials confirmed the safety and feasibility of some kinds of cell therapy in stroke patients (Kalladka D et al., 2014). Cell therapy involves the delivery of cells locally (eg, direct intracerebral implantation), intrathecally or systemically (eg, intravenous or intra-arterial).

G-CSF has been shown to be safe in Phase I clinical trials of human stroke when used within 7 days (Shyu WC et al., 2006; Zhang JJ et al., 2006) or 7-30 days post-stroke (Sprigg N et al., 2006). Low-dose G-CSF (150 and 300 µg/body/day) was safe and well tolerated in acute and ischemic stroke patients (Moriya Y, et al, 2013). Another randomized, double-blind, placebo-controlled trial suggests that a higher dose of G-CSF (10µg/kg/day) is safe when administered in subacute stroke (England TJ et al., 2012).

However, although there was a trend for reduced infarct growth, G-CSF treatment failed to show efficacy in functional evaluation in a large Phase 2 trial in acute ischemic stroke patients (Ringelstein EB et al., 2013). Compare to GSF, exogenous cell therapy is the main focus for developing new treatment for stroke.

3.2.2.1. Bone Marrow Mononuclear and Stromal cells (BMMNCs and BMSCs)

BMMNCs and BM-BMCs in Acute/Subacute Stage of Stroke

Intra-arterial autologous BMMNCs transplantation was performed for acute ischemic stroke (Mendonça et al., 2006; Moniche F et al., 2012; Friedrich M et al., 2012). Patients demonstrated a partial improvement and a slight decrease in the ischemic area by MRI and hypoperfusion by SPECT, even for patients with moderate to severe acute middle-cerebral-artery strokes. Cell therapy is also safe, feasible and effective via an intravenous route of administration (Savitz S et al., 2011) and for patients with subacute ischemic stroke (Honmou O et al., 2011).

BMMNCs and BMSCs in Chronic Stage Of Stroke

An early tissue distribution of BMMNCs was reported in a chronic stroke patient after intra-arterial delivery (Barbosa da Fonseca LM, 2009). Part of the cell suspension was radio-labeled with ^{99m}Tc to monitor the fate of transplanted BMMNCs. Brain SPECT views revealed uptake and retention of the labeled BMMNCs in the territory of the left MCA for up to 48 hours. The remaining uptake occurred mainly in the liver and spleen. This distribution is consistent with Correa's report (Correa PL, 2007).

Autologous BMMSCs were injected intravenously into 12 patients with stroke. Serial evaluations showed no severe adverse cell-related effects and a trend of functional recovery (Honmou O, 2013) and similar results were reported by intravenous cell transplantation (Bringas ML et al., 2011; Alvarez-González et al., 2009) and also by intra-arterial cell transplantation (Battistella et al., 2011). Long-term follow-up is, however, required to provide convincing evidence for its safety (Lee J et al., 2010). Additional studies are in underway (Kim S et al., 2013).

3.2.2.2. Neurons Derived from Teratocarcinoma

Kondziolka et al. (Kondziolka D et al., 2000) studied the safety and feasibility of intraparenchymal transplantation of neuronal cells derived from human teratocarcinoma in twelve patients with basal ganglia stroke and fixed motor deficits. No adverse effects were observed during a 12-month follow-up.

The European Stroke Scale score improved in six patients, and six of the eleven PET-scans performed six months after the procedure showed increased FDG uptake at the site of implantation. Nelson et al. (Nelson PT et al., 2002) reported the first postmortem brain findings for a patient 27 months after transplantation, who died of acute myocardial infarction. Neurofilament immunoreactive neurons were identified in the graft site, and fluorescent in situ hybridization revealed polyploidy in groups of cells at this site, and there was no evidence of a neoplasm after more than 2 years implantation. In a Phase 1 human trial, Kondziolka et al. demonstrated that (Kondziolka D et al., 2005), neuronal transplantation is feasible, safe and effective. In the following Phase 2 randomized clinical trial for human neuron transplantation combined with rehabilitation program, improvement of measurable movement and daily living activities were observed in some patients (Kondziolka D et al., 2005).

3.2.2.3. Umbilical Cord Stromal Cells

Umbilical cord stromal cells have been shown as a feasible and safe approach for the treatment of ischemic stroke with potential to improve the neurological (Jiang Y et al., 2013).

3.2.2.4. Autologous Peripheral Blood Stromal Cells

After G-CSF mobilization, intracerebral implantation of autologous peripheral blood stem cells has been shown safe, feasible and effective in stroke patients in a randomized phase II study (Chen DC et al., 2014). Wang L et al. indicated administration of G-CSF-mobilized autologous CD34 positive cells was safe in patients post stroke (Wang L et al., 2013).

Other Cell Type

Neurotransplantation of fetal porcine cells in patients with basal ganglia infarcts was demonstrated as safe and feasible in a preliminary study (Savitz S et al., 2005). Two patients showed improvement in speech, language, and/or motor impairments which persisted at 4 years.

Combination Cell Therapy

Bahasin A et al. (Bahasin A, 2013) recruited forty chronic stroke patients with treatment with autologous mononuclear and mesenchymal stromal cells intravenously. The safety test profile was normal with no mortality or cell related adverse reactions in patients, and statistical significant improvement by assessment of modified Barthel Index and an increased number of cluster activation in Brodmann areas BA 4, BA 6 in EEG was evident. Cell suspension consisting of cells from immature nervous and hemopoietic tissues was subarachnoidally transplanted to 10 stroke patients. The results showed significantly functional improvement six months after treatment (Rabinovich SS et al., 2005). A total of 10 consecutive stroke patients were treated by combination cell transplantation including olfactory ensheathing cells, neural progenitor cells, umbilical cord mesenchymal cells, and Schwann cells. After 6 months to 2 years follow up, the patients achieved different degrees of neurological function amelioration including improved speech, muscle strength, muscular tension, balance, pain, and breathing; most patients had an increased Barthel index score and Clinic Neurologic Impairment Scale score (Chen L et al., 2013).

3.2.3. Neuromodulation

The effects of repetitive transcranial magnetic stimulation (rTMS) on motor and sensory function recovery in stroke patients have been investigated. For hand motor function recovery after stroke, rTMS of the lesioned or contralesional motor cortex was combined with motor training and showed ambiguous effects; some patients improved, whereas others did not show any rTMS effect (Le Q et al., 2014). Central post stroke pain (CPSP) is one of the most refractory chronic pain syndromes. The rTMS of the primary motor cortex has been demonstrated to provide moderate pain relief for CPSP. The mechanism underlying the pain relief is due to restoration of abnormal cortical excitability (Hosomi K et al., 2013).

Transcranial direct current stimulation (tDCS), a non-invasive neuromodulation technique inducing prolonged brain excitability changes and promoting cerebral plasticity, is a promising option for neurorehabilitation, such as limb function and aphasia (JMonti A et al., 2013). The effects of rTMS/tDCS on the functional architecture of the motor system depend upon lesion location, degree of impairment and number of treatment sessions. Furthermore, analyses of regional brain activity and motor network connectivity allow prediction of the behavioral effects of brain stimulation (Grefkes C et al., 2012).

Robotic treatment is effective to reduce motor impairment in chronic stroke patients (Mazzoleni S et al., 2013). An electromyography (EMG)-driven hand robot developed for post-stroke rehabilitation training showed significant motor, spasticity and muscle coordination improvements in the hand (Hu XL et al., 2013). Another Hand Exoskeleton Rehabilitation Robot had benefits in range of motion, grip strength in the hands of post stroke patients (Godfrey SB et al., 2013). Robot-aided gait training could provide selective control on one of the essential subtasks of walking (B et al., 2013). In a prospective, multicentre,

parallel-group randomized trial enrolled patients with motor impairment for more than 6 months and moderate-to-severe arm paresis after a cerebrovascular accident in Switzerland; 38 patients assigned to robotic therapy had greater improvements in motor function in the affected arm over the course of the study. However, the authors pointed out that absolute difference between effects of robotic and conventional therapy was small and of weak significance (Klamroth-Marganska V et al., 2014). A tetraplegia patient with brainstem stroke could perform three-dimensional reaches and grasp movements using a neural interface system-based control of a robotic arm. Although robotic reach and grasp actions were not as fast or accurate as those of an able-bodied person, neural interface system is one of the potential treatments for disability caused by stroke (Hochberg L et al., 2012).

In conclusion, although there are major advances in understanding of the pathophysiology of cerebral ischemia, therapeutic options for acute ischemic stroke remain very limited. Consequently, successful treatment of acute ischemic stroke remains one of the major challenges in clinical practice. For the sequelae /of chronic stage of stroke, few of the treatment options have proven efficacious in clinical studies despite tremendous progress in preclinical studies. Cell-based neurorestorative strategies possibly offer the broadest range of potential treatments, because of multiple therapeutic options, such as cell types, routes of administration, therapeutic windows, and combination with other strategies. Cell therapy for stroke has demonstrated efficacy in the improvement of neurological outcome and quality of life of patients in the acute or chronic stage of stroke. Further investment in cell-based therapy for the neurorestorative treatment of stroke is therefore warranted.

ABSTRACT

Stroke represents the leading cause of disability among the elderly in the industrialized world. Indeed, no more than the 40% of the stroke survivors is able to walk independently, and/or to properly use the upper limb, and only after having performed an appropriate rehabilitative treatment. Moreover, post-stroke cognitive deficits, including aphasia, apraxia and neglect, and other neuropsychiatric abnormalities may negatively impact on patients' quality of life.

One key principle of post-stroke neurorehabilitation is the repetitive creation of specific learning situations to promote mechanisms of neural plasticity in stroke recovery. Indeed, there is growing evidence of achieving a better outcome of neurorehabilitation with early initiation of treatment, high intensity, with specific goals and active therapies, and the coordinated work and multimodality of a specialized team.

To this end, robotic neurorehabilitation has the potential for a greater impact on impairment due to easy deployment, its applicability across of a wide range of motor

* Corresponding Author's Email: salbro77@tiscali.it.

disability, its high measurement reliability, and the capacity to deliver high dosage and high intensity training protocols.

Aim of this chapter is to provide a comprehensive overview on the potential role of assistive technology in post-stroke rehabilitation, focusing either on robotic gait and upper limb neurorehabilitation or computerized cognitive rehabilitation. Emerging and promising tools, including telerehabilitation and Computer Assisted Rehabilitation Environment (CAREN), will be also discussed.

1. INTRODUCTION

Stroke represents the leading cause of disability among adults in the industrialized world. Although data trends indicate that stroke-related death rate is declining, the physical and psychological impacts following a stroke can be devastating [1, 2]. Indeed, even though about 80% of individuals with stroke survive to the acute event, only about 40% is able to walk independently, but only if they have performed an appropriate rehabilitative treatment [3]. The most common feature in patients affected by stroke is hemiparesis with spasticity, which is responsible of the typical postural pattern, with an asymmetric posture and a reduced weight-bearing on the paretic limb, severe balance dysfunctions, and an increased risk of falling [4]. Interestingly, up to 85% of the patients show an initial deficit in the arm, and three to six months later, problems remain in 55–75% of the patients[5]. Moreover, oropharyngeal dysphagia occurs in 45-65% of patients after acute stroke, being the most important risk factor for the development of pneumonia, which in turn accounts for about 30% of all stroke-related deaths[6].

Finally, about one-fifth of stroke survivors may experience mood and anxiety disorders [7], leading to worse functional outcomes, whereas approximately one-quarter of these patients may develop dementia [8]. Other cognitive impairments, including attention, language, and executive function impairments occur in around 50% of stroke survivors [9]. The need of an appropriate rehabilitative approach to the treatment of motor disorders is widely recognized, since the type of training strategy adopted can significantly influence the degree of motor recovery [10]. Moreover, cognitive rehabilitation and a proper treatment of post-stroke depression may significantly improve patient's training participation, and thus functional outcomes [11].

Recovery from a stroke event is a complex process, likely occurring through a combination of spontaneous and learning mediated processes, whose knowledge is helpful in determining when to expect recovery and for planning appropriate treatment and timing of rehabilitation [12]. Although it is widely recognized that most spontaneous behavioral recovery tends to occur within the first 3 months after stroke onset, different patterns of recovery, depending on many complex factors, may extend this period [13]. Indeed, cerebral plasticity may be present also in chronic stroke patients, as evaluated by transcranial magnetic stimulation and advanced neuroimaging techniques [14].

Patients' improvement after rehabilitation increases with the training intensity and is related mainly to the tasks practiced during therapy. To this end, robotic neurorehabilitation has the potential for a greater impact on impairment due to easy deployment, its applicability across of a wide range of motor impairment, its high measurement reliability, and the capacity to deliver high dosage and high intensity training protocols.

2. ROBOTIC VERTICALIZATION

Although physical therapy may be beneficial in limiting the effects of bedridden condition and stroke medical complications and facilitating maximal functional recovery, mobilizing severely impaired or non-cooperating patients is often unprofitable. In order to improve and standardize physiotherapy-assisted VT (pVT), several robotic devices have been developed. In particular, the ERIGO device (Hocoma AG, Volketswil, Switzerland) combines progressive verticalization, cyclic leg movement (which allows stepping reinforcement in combination with step synchronized muscle functional electrical stimulation -FES- at lower limb), and body weight loading to ensure the safe stabilization in the upright position of the patient).

Figure 1. A patient affected by severe stroke during Erigo training.

FES combined with passive stepping movements may be an effective modality to increase circulating blood volume and thereby tolerance to postural hypotension in healthy subjects. Notably, FES stepping has been shown to be an effective tool for muscle strengthening and walking improvement in neurological patients, including hemiplegic ones [15-17]. Indeed, robotic verticalization (rVT) shows many advantages in comparison to pVT, e.g., the body weight loading and the possibility to continuously perform cyclic leg movements in addition to FES. More in detail, rVT maximizes the potential for longitudinal weight bearing through the lower extremities in a position of hip-extension/knee-extension/ankle-dorsiflexion, which is difficultly obtained in the pVT setting. Moreover, rVT allows strengthen exercises of body weight shifting from one leg to the other, which are not

simply carried out in severe post-stroke patients. Nevertheless, the presence of the physiotherapist is always essential, since patient's cooperation has to be constantly ensured and stimulated [18-19].

3. ROBOTIC GAIT TRAINING

Over the past years, beyond conventional physical treatment, a variety of new rehabilitative strategies, including gait training on treadmill with body weight support (BWS), have been carried out, demonstrating their effectiveness in improving walking performances [20]. A recent systematic review provides evidence that the use of electromechanical-assisted gait training devices in combination with physiotherapy increases the chance of regaining independent walking ability for people after stroke. Such effectiveness has been mainly demonstrated concerning the acute and subacute post-stroke phase, but the role of robotic-assisted gait rehabilitation in chronic stroke is still underdebate [21].

Two groups of robotic-assisted devices were developed: end-effector type and exoskeleton type (9-11) [22].

3.a. End-effector Devices

End-effector devices work by applying mechanical forces to the distal segments of limbs whereas exoskeleton-type devices have robotic arms aligned with the anatomical axes of the subject thus controlling proximal and distal joints. The end-effector type includes mainly the "*Gait Trainer*" (GT) (Reha-Stim; Berlin, Germany) and the "LokoHelp" LokoHelp group; Weil am Rhein, Germany. The GT includes a system for BWS and two footplates to which the patient's feet are fixed by straps. The plates are positioned on two bars, two rockers and two cranks that provide the propulsion thus simulate gait like movements. A recent study has demonstrated that GT-BWS walking training might be safer than overground walking training in subacute stroke patients, as evidenced by less patient's cardiometabolic demand.

The "LokoHelp" device is fixed onto the band of the treadmill and transmit the treadmill movements to levers positioned on both side of the device.

3.b Lokomat

The prototype of the exoskeleton type is the Lokomat (Hocoma; Zurich, Switzerland). The Lokomat is the most advanced robotic technology available for gait training and neurological re-patterning. While suspended above a treadmill in a secure and stabilizing harness, the user's legs are secured to the Lokomat's robotic legs. The controlled motion of the robotic legs guides the user's legs in an efficient and effective gait pattern. This motion, in addition to weight bearing through the legs, stimulates repatterning of the central nervous system. Speed, ROM, body weight support and guidance are all controlled by the therapist through an advanced software, and the Lokomat charts user progress with measurements for stiffness, strength, range of motion and distance. Compared to *Lokomat Nanos*, the newer

Lokomat-Pro exercises in a virtual reality environment with a constant audio and visual feedback (Figure 2).

Figure 2. Lokomat-Pro gait training in our Research Neurorehabilitation Laboratory.

Several controlled trials showed a superior effect of Lokomat in acute stroke patients with respect to walking ability and velocity as patients walk more symmetrically, with higher speed and a more efficient gait [23-25].

Kelley et al. [26] in their blinded randomized clinical trial have found no significant differences in gait velocity, endurance, or functional level between the two groups of chronic stroke survivors undergoing either Lokomat or traditional over-ground gait training.

Moreover, Hornsby et al. [27] showed greater improvements in speed and single limb stance time on the impaired leg in those subjects who received therapist-assisted locomotor training, with an interesting improvement on the perceived rating of the effects of physical limitations on quality of life only in individuals with severe gait deficits. On the contrary, a recent study by Ucar et al. [28] has demonstrated a significantly improvement on walking speed in patients affected by post-stroke chronic hemiplegia undergoing Lokomat training than those performing traditional training.

We have recently demonstrated that Lokomat training may improve mood, coping style and, maybe, also cognitive performance beyond the motor functional status. We have indeed postulated that the positive impact of LOKOMAT on mood and coping styles may be partly related to the task-oriented exercises with computerized visual feedback, which can be considered as a relevant tool to increase patients' motor output, involvement, and motivation during gait training [29]. Moreover, we have also argued that the effect of this advanced robotic gait training on cognition was due either to the improvement in attention/motivation (integrated biofeedback system monitors the patient's gait and provides real-time visual performance feedback to motivate the patient for active participation) or in mood, as depression may worsen cognitive impairment.

4. UPPER LIMB ROBOTIC REHABILITATION

Current upper-limb systems can be divided into two types: end-effector, including MIT/IMT-Manus, MIME, GENTLE/s, and exoskeleton, such as ARMin, Pneu-WREX, RUPERT, REHAROB) [30]. With end-effector systems, subjects hold a manipulandum that experiences robot-imposed forces. Therefore, all the forces and measurements are at a single interface that has the advantage of easy set-up for patients of different body sizes. An analysis of three studies that used different kinds of end-effector system (MIT-Manus, ARM Guide, MIME) did not show a significant difference with respect to ADL measures (i.e., FIM score), although comparisons at the level of impairment have not been made, nor between training in 2 versus 3 dimensions. With exoskeletal systems, the limb is enclosed in an actuated robotic suit conforming to the configuration of the limb. While a subject's limb can be constrained with an end-effector system to specify one limb configuration (e.g., ARM Guide), the mechanical flexibility of the exoskeletal type allows full specification of limb configuration and for forces to be applied and measured independently at each joint [30]. Exoskeletal systems have the advantage that forces can be applied and measured independently at each joint. To date, no studies have directly compared the two types of robotic system of system but differences can be expected based on motor control principles.

4.a. Armeo

The Armeo Therapy Concept improves the efficiency of therapy treatments because the exercises are self-initiated, self-directed, functional and intense. Interestingly, even severely impaired patients can practice independently, without the constant presence of a therapist, allowing patients to exploit their full potential for recovery [31].

The *ArmeoPower* has a robotic arm exoskeleton, with an electric lifting column for comfortable height adjustment, allowing active arm support in a large 3D workspace. It can be used for both the left and right arm and hand, and is adjustable to different arm sizes and to the height of the patient. A positioning system correctly aligns the shoulder joint for ergonomic actuation and the product promotes movement in all relevant joints, assessing torques and angles for shoulder, elbow, forearm, and wrist ROM.

The *ArmeoSpring* is specifically suited for patients who are beginning to regain active movement of the arm and hand, and has already proved to be successful in many clinics worldwide (Figure 3).

The Augmented Performance Feedback provided by the shared software platform, encourages and motivates patients to achieve a higher number of repetitions, and this leads to better, faster results and improved long-term outcomes.

The software also provides automatic, ongoing assessment of motor functions and patients can readily track their progress, helping them to grasp the initiative and reach towards recovery.

To date, only few studies have investigated the effect of such devices on stroke patients.

Figure 3. Post-stroke upper limb rehabilitation by using Armeo Power and Spring.

In particular, Colomer et al. [32] have found that Armeo® Spring is an effective tool for rehabilitating the affected arm in patients with hemiparesis secondary to ictus, even in the chronic stage.

5. FES-CYCLING AND BEYOND

Cycling exercise completed using a bicycle ergometer is usually used to supplement functional ambulatori training. The kinematic pattern of cycling exercise is very similar to that of walking; however, cycling exercise requires less balance capacity. Both walking and cycling exercise are cyclic and require the alternate muscle activation of antagonists of lower extremities in a well-coordinated manner. The intensity of cycling exercise can be controlled, and has been suggested to improve functional mobility, as well as balance, of stroke patients [33-34]. Other studies have reported that repetitive passive movement of spastic muscles can increase range of motion and reduce stiffness in the hypertonic joints of stroke patients [35-36]. The aforementioned studies also suggest that cyclic leg movement may provide a potential therapy for reducing hypertonia, one of the factors that prevent functional activity in stroke patients. The positive effect of cycling in hemiparetic patients is greatly potentiated by the use of Functional electrical stimulation (FES). In FES, computer technology sends low-level electrical impulses to specific muscles in patient's legs, arms, hands or other areas. The electrical stimulation can cause muscles to contract, which may promote increased muscle bulk or muscle control, and thus, may improve ROM, strength, and the functional use of hands, arms or legs. Previous studies have reported that functional tasks performed by hemiplegic hands show improvement after electrical stimulation treatment [37]. FES has also been used to improve walking ability in stroke subjects [36]. Moreover, the benefits of FES-

assisted cycling exercise include enhanced muscle strength and endurance, increased bone density, cardiopulmonary improvement, spasticità relief, and many other physiological and psychological advantages. Recently, similar FES-assisted cycling devices have been used for stroke patients, concluding that short term cycling training (with or without FES) is a useful therapeutic approach to reduce spasticity in stroke patients [35-36].

6. VITALSTIM

VitalStimtherapy is a special form of neuromuscular electrical stimulation (NMES) device, which has received FDA clearance to be used for treatment of pharyngeal dysphagia. It can only be administered under the direction of certified healthcare professionals (speech language pathologists and occupational therapists). VitalStim is a dual-channel electrotherapy system, which uses small calibrated electrical current delivered by specially designed electrodes to stimulate the muscles responsible for swallowing. At the same time, trained specialists help patients “reeducate” their muscles through rehabilitation therapy. A recent meta-analysis of the published literature has confirmed that no adverse events were identified and attributed a statistically significant positive treatment effect favoring the use of NMES on the throat in the rehabilitation of dysphagia [38].

Moreover, data by Li et al. [39] suggested that VitalStim therapy coupled with traditional swallowing therapy may be beneficial for post-stroke dysphagia. The mechanism by which Vitalstim may act in improving dysphagia could be related either to the repetitive and intensive swallowing exercises or to the electro-stimulation-induced of cortical plasticity.

7. COMPUTERIZED COGNITIVE REHABILITATION

Cognitive rehabilitation (CR) is a therapy to help brain-injured or otherwise cognitively impaired individuals to restore normal functioning, or to compensate for cognitive deficits [40].

The process of Cognitive Rehabilitation (CR) involves assessment of cognitive functions, identification of specific areas of impairment, goal setting and institution of appropriate rehabilitation techniques. Neuropsychological assessment is the first element of CR, necessary to establish the area of functional, emotional and behavior impairments and to serve as the basis for treatment planning. The computer-assisted cognitive rehabilitation (CCR) focus on similar neuropsychological processes but use computerized exercises that train attention and concentration, executive skills, perceptual motor skills and problem solving skills in game - like programs. CCR involves multimedia and informatics resources with the direct use of peculiar hardware systems and softwares, i.e., programs to reactivate neuropsychological performances compromised [41-42] (Figure 4).

Two types of CCR, i.e., the task-specific and the hierarchical approach, have typically employed different intervention approaches. In the specific approach, individuals are administered computer programs targeting specific cognitive deficits (for example, if the individual has attention problems, he/she will receive programs that reportedly train attention). In the hierarchical approach, individuals are trained on a sequence of programs that

are arranged hierarchically, training from fundamental to more complex cognitive functions (for example, the individual starts CCR with programs targeting attention, then moves up to visual spatial and perception, followed by memory retraining and, lastly, complex problem-solving programs) [43]. A recent Italian computerized cognitive tool, named ERICA, is used in the treatment of the cognitive dysfunctions following stroke. It includes a series of informatics exercises that are organized in five specific-domain (attention, memory, spatial cognition, verbal and non verbal executive functions), and finalized to stimulate the residual cognitive abilities post-stroke (Inzaghi, 2013). Another peculiar rehabilitative software, i.e., “Power-AFA”, is used to stimulate the language abilities (in production and comprehension) for the aphasic subjects.

Figure 4. A post-stroke patient CCR training at our Behavioral and Cognitive Laboratory.

As compared to conventional treatment, CCR has been demonstrated to be a promising methodology to optimize the rehabilitation outcomes following stroke [44].

8. VIRTUAL REALITY

Virtual Reality (VR) is a computer-simulated environment that can simulate physical presence in places in the real world or imagined worlds. Virtual reality can recreate sensory experiences, which include virtual taste, sight, smell, sound, touch, etc. Most current VR environments are primarily empirical experiences, displayed either on a computer screen or with special stereoscopic displays, and some regulated simulations include additional sensory information and emphasise real sound through speakers or headphones targeted towards witnesses [45]. Some advanced, haptic systems now include tactile information, generally known as force feedback in medical, gaming and military applications. The introduction of VR augmented sensorimotor rehabilitation was heralded as a therapy that promised ecologically valid, intensive task specific training. Additionally, it was suggested that VR

could deliver training intensity (repetitions and duration) associated with neuroplasticity and positive behavioral adaptations because it was particularly well suited to very high training doses [46].

The Virtual Reality Rehabilitation System (VRRS, by Khymeia Group) VRRS is based on previous research performed at the Department of Cognitive Science at MIT Massachusetts Institute of Technology in Boston. VRRS is conceived to put the patient in a situation to generate the augmented feedback towards his central nervous system (augmented feedback) through exercises performed in a virtual environment which help to develop knowledge of results of the movements (knowledge of results) and knowledge of the quality of the movements (knowledge of performance). A recent study has demonstrated that the reinforced feedback in virtual environment (RFVE) is more effective than traditional rehabilitation for the treatment of upper limb motor function after stroke, regardless of stroke etiology (i.e., ischemic, hemorrhagic) [47].

Moreover, VR exercise intervention for inpatient stroke rehabilitation has been found to improve mobility-related outcomes [48].

Following about 10 years of development and clinical trials, many prestigious international scientific publications have been released among which the Cochrane Review (the most authoritative international organization for evaluating clinical methods and medical devices) that has shown the fact that the virtual reality technology applied to neurological motor rehabilitation has a greater effect than using just the traditional rehabilitation [46].

9. TELEREHABILITATION

Telemedicine is defined by the American Telemedicine Association as the use of medical information exchanged from one site to another via electronic communications to improve patients' health status. Telerehabilitation (TR) is defined as rehabilitation specialists involved in applying computer-based technologies and telecommunications to improve access to rehabilitation services and to support independent living. This particular application of telemedicine exploits several aspects of rehabilitative medicine at a distance: tele-monitoring (patient assessment functioning and clinical management), teletherapy, tele-consultation, tele-mentoring and tele-education for professionals and caregivers [49].

Several National Health System guidelines recommend a reduction in the duration of patients' stays in hospital in order to minimize expenditure; with this in mind telemedicine could be utilized in facilitating early discharge support. A recent review of early discharge support post-stroke

illustrated that patients with mild to moderate disability were significantly less likely to be dead or dependent by the time of their scheduled follow-up, in comparison with those who received conventional care [50].

TR has been demonstrated to be a successful tool in improving the physical and cognitive outcomes of patients suffering from stroke. Through implementing the tele-cognitive rehabilitation activities, therapists can help patients to practice, and thus improve, their motor and cognitive skills [51]. Different studies have indicated a high possibility of accessing tele-rehabilitation services to enhance, in particular, memory, attention, problem-solving, and activities of daily living.

However, a recent systematic review has found insufficient evidence to reach conclusions about the effectiveness of telerehabilitation after stroke. Moreover, no randomised trials that included an evaluation of cost-effectiveness were found. Therefore, which intervention approaches are most appropriately adapted to TR remain unclear, as does the best way to utilise this approach.

10. CAREN

The (Computer Assisted Rehabilitation Environment) CAREN system, developed by MOTeK Medical (Amsterdam, Netherlands) consists of a motion capture system and a base driven by hydraulic and mechanical actuators. The CAREN system may also be equipped with varying degrees of virtual reality immersion ranging from a flat video, dual-channel audio, theater in its “base” model to a 360°, surround sound dome enclosure in its “high end” version. Real-time motion tracking technology enables the CAREN system to follow patient movements frame-by-frame for detailed kinematic and biomechanical analysis using up to 24 mounting locations. Numerous studies have also been conducted assessing over ground walking vs. virtual reality treadmill-based rehabilitation indicating that the CAREN system is an effective rehabilitation aid for patient assessment. The CAREN system is unique in that it allows the subject to be immersed in a realistic clinical environment, while therapist and physicians collect kinematic and kinetic data in order to plan future rehabilitation regimens.

The tool was first developed for the rehabilitations of wounded warriors [52].

Indeed, in everyday life, warfighters with lower extremity trauma may experience uneven terrain, cracks in pavements, slippery conditions, etc. – all potential scenarios that would increase fall risk or injury. However, when using the CAREN system, specific physical perturbations may simulate these environmental conditions in a more safe and controlled setting, and thus, new rehabilitation methods and gait/ prosthetic limb training may be developed for these individuals to mitigate falling risks outside of the clinic [53-54]. Although the applications for the CAREN system have continued to demonstrate how this rehabilitation tool is an important element in wounded warrior care, one distinct advantage of this system is that it provides physical and cognitive aid for those with multitrauma and traumatic brain injury, with emerging promising data also in stroke patients [55].

CONCLUSION

To ensure that after a stroke, people can return to a life that is meaningful to them and resume previous roles, rehabilitation needs to be either an intense or a lifelong process and should not stop at 3 months or at the end of formal rehabilitation programmes.

To provide ongoing rehabilitation in a sustainable way, a low-cost and effective delivery method needs to be found. Using assistive technology will improve patient's outcomes and reduce the cost of intervention.

Moreover, the use of telehealth systems will allow treatment to continue for longer, which may facilitate the transition from hospital to home and encourage people to direct their own rehabilitation in the longer term.

ABSTRACT

Stroke is the second most common leading cause of death in the world. Stroke could be classified into ischemic stroke, intracerebral hemorrhage and subarachnoid hemorrhage. Vascular imaging of stroke is crucial for early detection of primary and secondary causes of stroke. Digital subtraction angiography (DSA) has been regarded as the gold standard imaging method of choice in all patients with stroke. In this review, we have described the updated information of clinical and technical implementation of DSA in stroke imaging. The clinical utilities of DSA in imaging of carotid stenosis and implementation of contemporary DSA techniques in subarachnoid hemorrhage were also reviewed.

CAROTID STENOSIS

The measurement of internal carotid artery stenosis is one of the most important assessments made when symptomatic patients are considered for prophylactic internal carotid

endarterectomy. Several different methods for measuring the degree of stenosis from carotid angiograms have been evolved, each holding varied definitions of what constitutes carotid stenosis. It is thus possible for the same angiogram to be reported as showing differing degrees of stenosis depending upon the particular method of measurement used. This is a potential source of confusion and frustration for both clinicians and researchers involved in this area. A uniform approach for the measurement of carotid stenosis is required, but a precise method to be adopted still remains to be declared.

Any method of measuring carotid artery stenosis, in this context, should first be shown to reliably predict the risk of ipsilateral ischemic stroke. The degree of ipsilateral carotid stenosis, as measured by the techniques used in the ECST[1] and NASCET, [2] has been clearly shown to predict stroke risk. More recently, the predictive powers of these methods and of the common carotid techniques have shown to be almost identical. Provided that there are no actual differences in the predictive power of these caliper techniques, the reproducibility of measurements by each technique becomes the significant issue. The aim of this study was to compare the reproducibility of these caliper techniques by assessing observer variability in reporting both intra-arterial DSAs and MRAs. The visual impression of stenosis, or “eyeballing” the degree of stenosis, remains a widely used technique by which angiograms are assessed in routine clinical practice.

In some recent in vitro studies, it has been illustrated that even though the accuracy rate of DSA is dependent upon the physical characters of the lesions, it exhibited more significant detection of severe stenotic lesions of about more than 70% over CTA and MRA between which no big difference was observed.[3] Despite, many utilities, accuracy of MRA still remains deficit for the surgical requisites determination in most cases of urgencies, further adjuring supplementary imaging analysis for confirmation.[4] Other advanced imaging technologies which could be augmented include digital ultrasonography(DUS), MRA with gadolinium contrast, and DSA. CEMRA(Contrast Enhanced Magnetic Resonance Angiography) could be an improved diagnostic in the determination of the severity of stenotic lesions and may even be much more efficient especially for the plaque morphology and is almost analogous to DSA and CTA.[5]

In another similar approach to describe the efficiency of different imaging techniques declared CTA (Computed Tomography Angiography) to be the most accurate method for the emergent diagnosis of carotid stenosis in contrast to MRA and DUS .Whereas showed an approximate analogy with blood-pool CEMRA.[6]

In a sixty-seven patients' set up, the approach of the techniques were substituted by their integrity and creditability to aid patient's interests and demands. It also emphasized upon alternate risks when intervened solely or in combinations as an alternative for DSA. With an accuracy rate of 80%, CTA, MRA and DUS showed close diagnostic alliance to DSA, independent of the surgical requisites but remained limited to the symptomatic carotid stenosis only. Thus, DSA still remains indispensable choice of investigation for carotid stenosis in a well equipped clinical set-up.[7-8]

Duplex ultrasound (DUS), magnetic resonance angiography (MRA) and computed tomography angiography (CTA) could also be beneficial for the follow up procedures succeeding a carotid endarterectomy in patients who have had an episode of stroke .While CTA and MRA aids a very clear 3D structures of the extra-cranial vessels, DSA-MRA privileges an extensive evaluation. These recent cost effective and non-invasive techniques

eventhough cant be relied upon completely but have successfully been able to gradually reduced the implementation of DSA pre-operatively under certain circumstances. [9-10]

MRA and CTA, both seem to share an approximate precision of $\geq 95\%$ in difference to DSA for assessment of carotid stenosis. [11] While the combination of DUS and CEMRA is beneficial for most of the typical cases of strokes, a consolidated data gained through DUS and CTA could be preferred for suggesting the need for surgical interventions with an extensive assessment.[12]

In case of advanced sub-arachnoid hemorrhage, an assisted DSA with Rotational Angiography (RA) surpasses the benefits of using it alone. Since 3D RA shows more specificity to aneurysms, offers a sophisticated pre-operative approach.[13] Another research revealed that the chances of errors could possibly be reduced by using any of these above mentioned techniques in a combination with DSA imaging but cannot be diminished completely.[14]

CEREBRAL ANEURYSMS

2D versus 3D DSA

2D DSA fails to expose the concealed vessels and their associated branches. On the other hand, 3D DSA commences a broader aspect of visualization for all super-imposed intracranial blood vessels. [15]

Certain parameters such as the size of the aneurysmal neck feeds as a significant base for the judgment of an aneurysm and for anticipating peri-operative procedures.[16] For this purpose, wide spread use of 2D and 3D DSA have been very helpful. Recent development of 3D DSA has lead to many comparative studies with previously existing methods of imaging including 2D DSA. Most researchers found 3D DSA to mimic 2D DSA images in many aspects but distinct provision of higher power of resolution.[17-18] 3D DSA is a comparatively rapid technology requiring a lower amount of radiation and contrast material.[19] 3D DSA magnifies the neck of an aneurysm more than 2D DSA, thus results in a mean difference of about 15% between both ratios.[19-20]Due to this fact, in spite of the presence of a highly advanced 3D DSA, 2D DSA remains popular than 3D DSA in most clinical settings due to the fact that it is more advantageous in many aspects such as quality, resolution, and limited need for further processing where 3D DSA remains deficient.[21]Risk of brain stem infarctions are examined via information from the study of the pontine arteries and their parallel circulations. Both 2D DSA and 3D-DSA are of equal importance for this approach of study. [22]

In a follow up set up, exploration of intracranial aneurysms succeeding an endovascular therapy was performed in which 3D DSA images outweighed that of 2D DSA. This study agreed with the use of 3D DSA over 2D DSA for predicting the rate of recurrences in high risk patients. [23]

3D DSA versus CTA

CTA is the gold standard choice for screening of acute onset of aneurysmal SAH. [24] But cannot be preferred as a primary choice for investigation of aneurysms preceding or following an endovascular therapy for an extensive assessment of anatomy of intra-cranial vasculature. [25] It is highly specific for the evaluation of severity of carotid stenosis. [2, 26] TA cannot provide enough evidences for minor bleeds. It is more likely to miss the detection of very small aneurysms sized <5mm. [27]

The exposure to radiation is roughly similar to DSA. CTA provides the maximum data without any threat of iatrogenic stroke since it doesn't include direct vascular interventions unlike DSA. On the contrary, DSA surpasses CTA as it helps to observe arteriovascular malformations (AVMs) and fistulas at controlled time intervals. [28]

3D DSA versus MRA

Blood-pool-enhanced MR angiography, is one the latest advanced MRA method which could also be implemented for a detailed assessment of the severity of carotid stenosis. [29] 4D DSA, briefly conferred as a 3D DSA process at regular intervals following the contrast flow pattern; proved to be a redeemed mode of imaging which is programmed favorably for an extensive access to the AVMs and remains unbiased upon the direction and thus, independent of all the intervening intracranial structures. It has been able to surpass all other previous conventional methods for this purpose. Further, the obtained data from a 4D DSA helps revealing all concealed information relevant to a stroke. This study needs to be emphasized upon in future for its other benefits. [30]

COLLATERAL CIRCULATION

DSA is the gold standard method of choice for imaging of collateral circulation in patients with stroke. Cerebral collateral circulations can be categorised into primary and secondary collaterals. Primary collaterals refer to the components of the circle of Willis and the ophthalmic artery and leptomeningeal blood flow constitute secondary collateral vessels. [31,32] Leptomeningeal collateral is associated with infarct growth and outcome in patients with acute ischemic stroke. [33] Good leptomeningeal collateral is reported to predict better outcome after acute ischemic stroke, even adjustment for known prognostic factors. [34] The underlying mechanism might be that good collateral flow maintain the ischemic penumbra before reperfusion.

Although several imaging method have been utilized in evaluation of collateral flow in patients with stroke, DSA remains the gold standard imaging method of choice. DSA can visualize the extent and number of collateral flow. TIMI Grade Flow is the most commonly used scoring system for evaluation of collaterals in patients with acute myocardial infarction and stroke. [35] It is originally derived from patients with cardiovascular disease. Now, the scoring system is widely used for assessment cerebral collateral flow. The TIMI grade ranges from 0-3 referring to levels of blood flow assessed during DSA. TIMI Grade 0 flow indicates

the absence of any antegrade flow beyond an occlusion. TIMI 1 flow is penetration without perfusion. The antegrade flow beyond the occlusion with incomplete filling of the distal vascular bed. TIMI 2 flow represents slow antegrade flow which completely reperfuse the distal artery. TIMI 3 is normal flow that lead to complete filling of the distal vascular territory.

Recently, CT angiography have been increasingly used in assessment of collateral flow.[35] Several leptomeningeal collateral scoring systems have been proposed and predict functional outcome. CTA source images were usually used to assess for the presence of collateral flow. The region of the Sylvian sulcus arteries were compared with the contralateral side. The grading system was based on the absence or presence of the vessels. However, considerable regional variability in the presence of these arteries were not considered in most scoring systems. CTA based collateral grading system has demonstrated good interobserver reliability and correlated with clinical outcome. The recent development of dynamic CTA imaging with perfusion imaging has greatly advanced the role of CTA in assessment of collateral circulation. MR angiography is less commonly used than CTA and DSA for assessment of collateral flows. 3D TOF or contrast-enhanced MRA are commonly used for visualization of collaterals. However, the signal intensity in is variable due to different acquisition methods.[37,38] TCD also provide noninvasive measurements of collaterals, but are less accurate than MRA. TCD is primarily used for evaluation of circle of Willis component vessels. The color-coded duplex ultrasonography may be improved with contrast administration.

ABSTRACT

Moyamoya is a cerebrovascular condition defined by the chronic progressive stenosis of the intracranial internal carotid arteries (ICAs) and their major branches. This stenosis predisposes patients to ischemic and hemorrhagic stroke resulting in focal disabilities and progressive cognitive impairment. *Moyamoya disease* predominately occurs in Asian children, and is now thought to result from a particular genetic mutation. This does not, however, explain the occurrence of moyamoya vasculopathy in many adults throughout the world. *Moyamoya syndrome* may occur in patients with other well characterized auto-immune diseases or coagulopathies. While the etiology of moyamoya remains unknown, there is an increasing body of literature that suggests inflammation contributes to its pathogenesis and/or progression. Studies have demonstrated smooth muscle cell proliferation and infiltrating T cells and macrophages in blood vessel walls, while other studies demonstrate elevated levels of endothelial adhesion molecules and cytokines in the cerebrospinal fluid and plasma of moyamoya patients. However, to more readily study the development and pathogenesis of moyamoya, and to create potential therapies for this condition, experimental animal models are needed. Here, we will review the transgenic mouse model engineered to study the genetic contribution to the disease, as well as describe the recently-developed surgical model to study moyamoya syndrome. Animal models can undergo similar radiologic imaging that is currently used to diagnose moyamoya and can be used to study the effects of inflammation on blood vessel function. Importantly, animal models can also be used to study the influence of moyamoya on cognitive impairment, an increasingly recognized chronic effect of the pathology. While moyamoya is a rare condition, the natural history can have a

devastating prognosis, and current treatment options are limited. Improving our knowledge about this condition will help in developing novel therapeutic approaches, and may help in understanding the role of neuroinflammation on carotid artery pathologies.

INTRODUCTION

The arterial blood supply of the brain and much of the spinal cord is derived from the internal carotid and vertebral arteries [1]. The internal carotid artery (ICA) ascends through each side of the neck and at the base of the brain gives rise to the ophthalmic artery, anterior choroidal artery, and the posterior communicating artery. It then bifurcates into the middle cerebral artery (MCA) and anterior cerebral artery (ACA), which supply blood to large portions of the frontal, parietal, and temporal lobes [1]. The ICA is divided into seven segments, as classified by Bouthillier et al., according to the anatomy surrounding the ICA and the compartments through which it travels; cervical, petrous, lacerum, cavernous, clinoid, ophthalmic, and communicating [2].

Moyamoya is a chronic cerebrovascular occlusive condition that predisposes affected patients to stroke in association with progressive stenosis of the supraclinoid segment of the ICAs and their proximal branches [3-5]. Reduced blood flow in these major arteries leads to ischemia, while the compensatory development of new blood vessels at the base of the brain leads to hemorrhage [3, 6]. The characteristic appearance of these abnormal neovascularizations was described on angiography as a “vague or hazy puff of smoke”, which is *moyamoya* in Japanese [7]. Extensive investigations of patients with this characteristic angiographic finding have been conducted over the past 50 years. Suzuki et al. divided the progression of moyamoya cerebrovascular pathology into six stages, including narrowing of the ICA and initiation of collaterals (stages 1-2), significant narrowing of the ICA and intensification of collaterals (stages 3-4), and complete blockage of blood flow through the ICA with concomitant disappearance of the collaterals with reliance on the external carotid branches to supply blood to the brain (stages 5-6) [7, 8]. During these various stages, patients suffer from headache, ischemic stroke, transient ischemic attacks (TIAs), seizures, and hemorrhagic stroke [4], which lead to focal disabilities and progressive cognitive impairment [9, 10].

Moyamoya disease (MMD) etiology remains unknown. However, there is a familial tendency in which individuals with a first-degree relative with MMD have an increased risk of developing the disease [11-13]. There is also a predilection for people of Japanese and Korean ancestry as disease incidence in East Asia is approximately 10 times higher than in Western countries [14]. Indeed, genetic studies have demonstrated possible linkage between markers located on several different chromosomes and familial occurrence [15-18]. In addition, studies identified the ring finger protein 213 (RNF213) gene as a susceptibility gene for MMD [19, 20]. Although hereditary factors may be involved in susceptibility to MMD, there are a growing number of cases that are sporadic. Moyamoya-like vasculopathies are now observed throughout the world in people of various ethnic backgrounds, including American and European populations [21-23]. These patients exhibit angiographic features of moyamoya vasculopathy along with other well-characterized system disorders; they are considered to have moyamoya syndrome (MMS). MMS-associated co-morbidities include hypertension, obesity, hyperlipidemia, thyroid disease, sickle cell disease, neurofibromatosis

type 1, Down syndrome, diabetes, and a variety of other auto-immune diseases [4, 12, 21, 23]. While an extensive number of reports exist to describe MMD, less is known about MMS. In fact, only recently have reports in literature begun to distinguish between the two. MMD incidence in the Japanese is calculated to be 0.35 per 100,000 population with a female-to-male ratio of approximately 1.8:1 [24]. In the United States (Washington and California), combined MMD and MMS incidence is reported to be 0.086 per 100,000 [25]. In Kentucky, however, a MMS incidence of 0.7 per 100,000 is reported [23], indicating regional differences. Moyamoya has a peak occurrence at two ages (children and adults), each with distinctive clinical presentation. Nearly half of MMD patients are diagnosed prior to 10 years of age and predominantly suffer from transient ischemic attacks, ischemic strokes, cognitive decline, epilepsy, and involuntary movements [8]. In contrast, adults diagnosed in their 20's – 40's commonly present with intracranial hemorrhage; this is the most common age group for MMS patients [5, 8]. While bilateral stenosis/occlusion of the ICA is most common in MMD, unilateral stenosis/occlusion can occur, especially in MMS patients [4].

The histopathology of moyamoya has been of interest for a number of years. Examination of the ICA and its major branches found a fibrocellular intimal thickening with proliferation of vascular smooth muscle cells [26-29]. Fibrin deposits, fragmented elastic lamina, and microaneurysms have also been observed [4, 5, 30]. These vessel pathologies are thought to be responsible for the stenosis and resultant ischemic and hemorrhagic stroke in these patients. In addition, the immune system may be a key factor in the pathogenesis and/or progression of moyamoya. Histopathological studies have shown macrophages and T cells infiltrate the thickened intima of occlusive vessels [27, 31]. Furthermore, immunomodulatory molecules such as soluble endothelial adhesion molecules and cytokines, as well as chemokines and growth factors are elevated in the cerebrospinal fluid (CSF) and serum of MMD patients, respectively [32-34]. The lack of animal models makes it difficult to ascertain the degree of involvement of inflammation and co-morbid conditions on the mechanisms of pathogenesis. In this chapter, we will summarize alterations in immunity in moyamoya (MMD and/or MMS) patients and how inflammation may contribute to moyamoya pathology. We will also discuss the advancement of animal models and how they may aid in the development of novel treatments or therapies.

INFLAMMATION

Inflammation is known to be an important factor in a wide variety of diseases. In the continued efforts to discover the etiology of moyamoya, the role of the immune system is gaining attention. However, it remains a great debate as to whether inflammation is a causal factor in moyamoya or if it is a result of the stenosis and ischemia associated with the condition. It is important to note that many previous investigations do not distinguish between MMD and MMS. Therefore, some cases as reported below to occur in MMD patients may, in fact, occur in MMS patients as well. We will review the immunological alterations that are observed in patients with moyamoya (Table 1) and its potential participation in the development and/or progression of disease.

Table 1. Immunological Changes in Moyamoya Patients

	Changes in MMD	Role in MMS	General role in inflammation	References
Leukocytes				
Macrophages	Increased in vessel walls; no change in the intima and tunica	Increased T cells in HIV-1 infected patients with MMS	Phagocytosis; Antigen presentation; Cytokine and growth factor	27; 35; 36
T cells	Increased in vessel walls, blood		Cytokine and chemokine secretion; Stimulation of antibody production; Recruitment of other immune cells	27; 31; 40
B cells	No change in vessel walls		Antibody production; Cytokine secretion; Antigen presentation	27
Cytokines				
TGF-β	Increased in blood, SMCs; No change in CSF		Anti-inflammatory	31; 41; 42
IL-10	Increased in blood		Anti-inflammatory	31
TNF-α	Increased in blood; no change in blood		Pro-inflammatory	31; 33
IL-17	Increased in blood		Pro-inflammatory	31
IL-6	Increased in blood; No change in blood		Pro-inflammatory	31; 33
IL-23	Increased in blood		Pro-inflammatory	31
IL-1b	Increased in blood		Pro-inflammatory	33
IL-2	No change in blood		Pro-inflammatory	31
IL-4	No change in blood		Pro-inflammatory	31
INF-γ	No change in blood		Pro-inflammatory	31
IL-8	No change in CSF		Pro-inflammatory	33
Chemokines and adhesion molecules				
ICAM-1	Increased in blood; Increased in CSF	Increased in CSF	Stabilizes cell-to-cell interaction; promotes leukocyte migration	31; 34
VCAM-1	Increased in blood; Increased in CSF	Increased in CSF	Promotes adhesion of leukocytes to vessels; promotes leukocyte	31; 34
E-selectin	Increased in CSF	Increased in CSF	Recruits leukocytes to the site of injury; mediates leukocyte "rolling"	34
CXCL5	Increased in blood		Increases chemotaxis of angiogenic neutrophils	49
CXCL12/ SDF-1α	Increased in blood		Activates and attracts lymphocytes; recruits EPCs from the bone marrow	50
CCL2/ MCP-1	Increased in blood		Recruits leukocytes to site of	33
Growth Factors				
VEGF	Increased in dura, glial cells, blood; decreased receptors; no change in CSF	Increased in the CSF	Promotes angiogenesis and vasculogenesis	33; 44; 52
bFGF	Increased in CSF, SMCs and ECs in STA, meningeal and vascular		Many mitogenic and cell survival functions	54; 55; 56
HGF	Increased with receptor in tunica media and intima, blood, CSF		Regulates cell growth, cell motility, and morphogenesis	44; 56
PDGF	Increased in blood		Regulates cell growth and division; in particular angiogenesis	33
G-CSF	Increased in blood		Stimulates hematopoietic cells from bone marrow into blood; promotes neutrophil survival, proliferation	
Other Factors				
sCD163	Increased in the blood		Soluble marker of cells of a macrophage lineage	32
Autoantibodies	Increased in the blood, CSF	Increased in the blood	Antibodies that target and react to a person's own tissue	62; 63; 64; 66

Leukocytes

Macrophages

Macrophages are an important component of the innate immune system and are responsible for phagocytosis of debris, dead cells, and foreign invaders. Their production of

reactive oxygen species, presentation of antigens to T cells, and secretion of soluble factors such as cytokines and growth factors can induce a diverse immune response [35]. It is thought that macrophages may be particularly relevant to MMD pathophysiology because of their role in another vascular disease, atherosclerosis, which is characterized by the deposition of lipids and resultant narrowing of arteries [27]. In this disease, macrophages penetrate the vasculature where they have both protective and pathogenic roles [35]. While it is unknown whether these factors hold true in MMD, there is conflicting evidence to suggest that macrophages are associated with the pathology.

One immunohistological study of the Circle of Willis isolated from 2 MMD patients post-mortem found very few CD68+ monocytes (i.e., macrophages) in the intima and tunica media [36]. However, Masuda et al. observed macrophages (subset not identified) that infiltrated the vessel walls of 6 MMD patients [27]. Interestingly, high concentrations of soluble CD163, a marker of activated M2 macrophages, has been measured in the blood of MMD patients [32, 37]. M2 macrophages exhibit diverse roles in vascular disease, including atherosclerosis, and are thought to be protective because of their anti-inflammatory nature and role in tissue repair [35]. However, one study found that CD163+ M2 macrophages from human atherosclerotic lesions correlated with pathological thickening of the intima and related stenosis, key features of MMD [38].

Given that MMD patients suffer from aberrant angiogenesis (excessive formation of collateral vessels) and increased vascular permeability, it is interesting to note that CD163+ M2 macrophages are also involved in intra-plaque angiogenesis and vascular permeability in atherosclerosis [38]. From these studies, we can conclude that macrophages have a complex role in the pathophysiology of MMD that cannot be labeled as exclusively protective or pathological. Additionally, increased levels of soluble CD163 in the blood of patients with MMD as well as autoimmune and inflammatory disease, indicates its potential to serve as a biomarker for pathogenic alterations to immunity during moyamoya [32].

T Cells

T cells are a type of white blood cell that are important for the adaptive immune response. Like macrophages, T cells are recruited to the blood vessel wall in vascular disease and have been found to infiltrate vasculature in MMD patients [27]. They respond to antigen presentation by macrophages and subsequently differentiate into various subtypes, such as effector, helper, or memory T cells [39, 40]. CD4+ T cells (i.e., helper T cells) play a critical role in immune protection and pathology by stimulating antibody production by B cells, recruiting other immune cells to the site of inflammation, and secretion of cytokines and chemokines [41]. Interestingly, significantly increased levels of CD4+ T cells have been found in the blood of MMD patients [31]. Given the diverse roles of CD4+ T cells in the immune system, the CD4+ populations were further divided into two subsets for analysis: Th17 cells and regulatory T cells (Tregs). Th17 cells are a pathogenic effector subset that contribute to inflammatory and autoimmune disease. The role of Th17 cells in vascular disease is controversial. In mouse models of atherosclerosis, blocking interleukin-17 (IL-17), the primary cytokine produced by Th17 cells, can either attenuate or accelerate atherosclerosis depending on the model used [40]. Circulating Th17 cells were shown to be increased in MMD patients, indicating the occurrence of systemic inflammation [31]. MMD patients also had increased levels of Tregs [31], an anti-inflammatory subset of T cells that counteract the immune response by preventing T cell proliferation, producing

immunosuppressive cytokines and counteracting autoimmunity [40]. While an increase in both pro- and anti-inflammatory T cell subsets seem contradictory, further analysis of the isolated Tregs showed they had a diminished suppressive function. In fact, the subset of Tregs identified in the MMD patients, known as FR_{III} (CD4⁺CD25⁺FoxP3^{low}CD45RA⁻), have an “unstable” phenotype and can transform into pro-inflammatory Th17 cells [40]. In addition, higher levels of Tregs were associated with more severe MMD, however no association between Th17 cells and disease severity was observed [40]. Elevated populations of T cells in the blood may be indicative of systemic inflammation in MMD patients and infiltration into the blood vessels suggest a role for T cells in moyamoya pathology.

Cytokines, Chemokines and Growth Factors

Cytokines

Cytokines are a broad class of small proteins that are important for cell signaling. They are produced by a wide range of cells, including immune cells and endothelial cells, and are important for the modulation of the immune system. Cytokines can be further broken down based on their function, cell of secretion, or target of action.

Cytokine concentrations in the blood and CSF of MMD patients also yield conflicting results. Transforming growth factor-beta (TGF- β), an anti-inflammatory cytokine produced by Tregs, was increased in the serum by three-fold compared to controls [41]. In addition, cultured smooth muscle cells (SMCs) derived from the superficial temporal arteries of MMD patients have increased expression levels of TGF- β , relative to healthy controls and patients with atherosclerosis [41]. However, TGF- β levels are not increased in the CSF of MMD patients [42], possibly suggesting a more systemic, rather than central, anti-inflammatory response for TGF- β . Additionally, IL-10 serum levels were also increased in MMD patients [31]. Its role in vascular disease is thought to involve the prevention of leukocyte-endothelial cell interactions and the inhibition of cytokine and chemokine production by other lymphocytes [43].

To further complicate our understanding of the role of cytokines in MMD, serum levels of certain pro-inflammatory cytokines (IL-17, IL-23, IL-1 β) are shown to be increased, while other pro-inflammatory cytokines (IL-2, IL-4, interferon (IFN)- γ) were not different from control patients [31, 33, 44]. Tumor necrosis factor-alpha (TNF- α) is elevated in the serum of MMD patients, however other investigators found no change [31, 33]. Finally, arterial SMCs treated with IL-1 β stimulated cell migration and DNA synthesis when the cells were derived from control patients, but had an inhibitory effect on cell migration and growth of the MMD patient cultures [45]. Taken together, this data suggests a complex interplay between pro- and anti-inflammatory cytokines in MMD patients that could be clarified by mechanistic neuroimmune studies in animal models of moyamoya.

Chemokines and Adhesion Molecules

A subset of cytokines, known as chemokines, have attracted interest from MMD researchers because they promote the migration and adhesion of leukocytes to vessel walls, as well as the diapedesis of immune cells into surrounding tissue, making them important during vascular disease [46]. Adhesion molecules, as the name implies, promote the adhesion of

leukocytes to vessel walls and, in conjunction with chemokines, promote the recruitment of leukocytes [47]. Chemokines and adhesion molecules are critical for the migration of leukocytes to vascular tissue and their role can be characterized in 4 major steps: (1) selectin-dependent tethering and rolling of the immune cell along the vessel wall, (2) adhesion via chemokines and their receptors, (3) integrin-dependent firm adhesion, and (4) egress across the endothelium [47]. MMD patients present with increased serum expression of intracellular cell adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1) [31]. ICAM-1, VCAM-1, and E-selectin are also increased in the CSF of MMD patients, providing support for the importance of adhesion molecules in both the periphery and CNS [34]. In murine models of vascular disease, treatment with VCAM-1 antibodies or VCAM-1 deficiency have been shown to be protective against atherosclerosis [47]. Genetic deletion of selectins in mouse models of vascular disease also induce protection, albeit to a lesser extent [47].

Changes in chemokine levels have been linked to MMD *in vivo* and *in vitro*. Studies report that while chemokine levels were not altered in the CSF of MMD patients [33], three chemokines were elevated in the blood [32, 48]. First, patients exhibit higher serum levels of CXCL5, a chemokine produced by both immune and vascular endothelial cells in response to pro-inflammatory stimuli [49]. CXCL5 promotes angiogenesis and neutrophil chemotaxis, both of which could contribute to MMD pathology, and has been linked to autoimmune diseases [50]. Second, patients exhibit higher plasma levels of CXCL12, a powerful chemotactic for lymphocytes. It modulates angiogenesis by promoting the trafficking of endothelial progenitor cells from the bone marrow to the peripheral blood [48]. Third, MMD patients present with increased plasma levels of CCL2 [33]. CCL2 deficiency or the genetic deletion of its receptor, CCR2, is protective in murine models of atherosclerosis, reducing lesion size and macrophage infiltration [46]. Additionally, *in vitro* studies found that co-cultures of endothelial colony-forming cells (ECFCs) and smooth muscle progenitor cells (SPCs) show a CCL5-dependent movement of SPCs [51]. SPC migration is increased in co-cultures from MMD patients, indicating chemokines may be consistently upregulated in MMD, further exacerbating vascular inflammation [51].

Growth Factors

Various growth factors have been shown to be increased in the CSF and blood of MMD patients, including vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF), platelet-derived growth factor (PDGF), hepatocyte growth factor (HGF), and granulocyte colony-stimulating factor (G-CSF). In fact, VEGF may play a central role in MMD pathology, as it stimulates pathological vasculogenesis, increases vascular permeability in intracranial lesions, and enhances angiogenesis during cerebral ischemia [28]. VEGF expression is also increased four-fold in the dura of adolescent MMD patients and was identified in glial cells of an adult patient with MMD [28, 52]. Increased VEGF expression correlates with higher levels of the aforementioned anti-inflammatory cytokine, TGF- β , as well as higher levels of matrix metalloproteinase 9 (MMP-9), an enzyme that degrades the extracellular matrix [31, 33]. The breakdown of the extracellular matrix can lead to vascular instability and increase the likelihood of hemorrhages. However, despite the higher levels of VEGF, soluble VEGF receptors are lower in MMD patients compared to healthy controls [53].

Another critical growth factor for the development of moyamoya may be bFGF, which enhances vascular smooth muscle growth [28]. Immunohistochemical examinations of surgical specimens obtained from MMD patients found that bFGF is overexpressed in multiple tissues, including the superficial temporal artery (STA), endothelial cells, SMCs, dura mater, and vessels of the Circle of Willis [36, 54]. High levels of bFGF may lead to vessel stenosis given that bFGF has also been found in abnormally thickened tunica media [42]. Additionally, two studies demonstrate elevated concentrations of bFGF in the CSF of MMD patients compared to atherosclerotic patients and healthy controls [55, 56].

Several other growth factors are also linked to MMD, including HGF, G-CSF, and PDGF. HGF stimulates proliferation of endothelial cells and migration of cultured arterial SMCs derived from MMD patients, making this yet another factor that could contribute to pathological angiogenesis [28, 57]. Nanba et al. determined that expression of HGF and its receptor c-Met are increased in the tunica media and intima of vessels from MMD patients [58]. Additionally, there is a higher concentration of CSF-derived HGF in MMD relative to patients with cervical spondylosis and internal carotid occlusions [44, 58]. G-CSF mobilizes hematopoietic stem cells in the bone marrow and promotes neutrophil survival, proliferation and differentiation. It can also promote angiogenesis, further linking it to MMD pathology. Serum levels of G-CSF were found to be 1.5-fold higher in children with MMD compared to healthy controls [59]. Finally, higher concentrations of PDGF in the plasma of MMD patients have been reported [33]. *In vitro* data indicate a complex relationship between SMCs and PDGF. SMCs derived from the superficial temporal arteries have a blunted response to PDGF, however, PDGF-receptors are downregulated in arterial SMCs isolated from MMD patients [60, 61]. Despite this, it appears PDGF still exerts a differential effect on MMD SMCs, as it stimulates cell migration to a greater extent than in control cultures [57].

Autoimmunity

Autoantibodies

MMD patients present with higher levels of circulating autoantibodies in the blood and CSF [62, 63]. Sigdel et al. found 165 autoantibodies with a greater than 2-fold change relative to control subjects. Some key autoantibodies they discovered in serum were the B-cell antigen receptor complex associated protein alpha chain (CD79A), ephrin-A3, which is critical for integrin-mediated T lymphocyte interactions, and CD7, a surface marker for cytotoxic CD8+ T cells [63]. Molecular pathway analysis showed that reactive antigens were involved in the following pathways: neurological disease, tissue development, cellular growth and proliferation, and muscular system development [63]. MMD patients had a higher antigenic response to proteins in the immunological and inflammatory response, including interferon and the tumor necrosis factor superfamily [63]. Other autoantibodies detected in MMD patients include a natural T cell toxic autoantibody, in the serum of 5 out of 23 patients [64], thyroid autoantibodies associated with “aggressive presentation” (i.e., hemorrhage, major stroke, transient ischemic attacks), and anti-thyroperoxidase antibodies that increased the likelihood of ischemic stroke in MMD patients [65, 66]. MMD autoantibody profiles of individuals with active disease compared to those that had received revascularization surgery found that post-operative patients had lower expression of autoantibodies compared to

individuals with active disease [63], suggesting that the vascular pathology induces an autoimmune response that can be countered by treatment.

Autoimmune Disorders and Other Predisposing Diseases

As mentioned in the introduction, moyamoya is associated with several predisposing diseases related to the immune system. There is a higher prevalence of autoimmune disorders, particularly type 1 diabetes and thyroid disease, in midwestern US populations [21, 66]. Similarly, in an epidemiological study of a Western Chinese population, there was a greater likelihood of type 1 diabetes and Graves disease in MMD patients relative to the general Chinese population [67]. In fact, the overall prevalence of autoimmune disease in MMD was up to 31%. Juvenile-onset autoimmune disease is also associated with MMD in both pediatric and adult patients [68]. Prior infections and chronic inflammation are also risk factors for MMD. Serum levels of *Propionibacterium acnes* (*P. acnes*) antibodies were higher in individuals with MMD compared to healthy controls [69]. When rats were infected with *P. acnes*, they developed MMD-like changes to their internal carotid arteries. Epidemiological studies show that many MMD patients have a history of inflammation above the neck, in particular, recurrent chronic tonsillitis [70]. Taken together, this suggests that prior inflammatory or autoimmune disorders could be predisposing factors that increase the risk for developing moyamoya, and specifically MMS.

Genetics

HLA

There have been many efforts to identify genetic risk factors that could predispose individuals to developing MMD. Many of the relevant genes identified have been linked to immune function. Several studies performed genotyping of type I and II human leukocyte antigens (HLA) in patients with MMD [71]. Molecules encoded in the HLA locus play many roles in the immune system: antigen presentation, inflammation regulation, the complement system, and innate and adaptive immune cell responses. HLA molecules are also critical for self/non-self-recognition and HLA polymorphisms are closely linked with many autoimmune disorders [72]. MMD studies found associations between HLA alleles and MMD in both Asian and Caucasian European populations [71]. While many alleles have been identified, the strongest candidate is HLA-DRB1*13, which was significantly associated with MMD in both Korean and European populations, with a higher frequency of this phenotype in MMD patients [73, 74]. Interestingly, the HLA-DRB1*13 allele is believed to be protective against other autoimmune disorders, as this allele is underrepresented in patients with systemic lupus erythematosus, psoriasis, rheumatoid arthritis, systemic sclerosis, multiple sclerosis, and myasthenia gravis [75]. However, patients with systemic lupus erythematosus possessing the HLA-DRB1*13 allele were at greater risk for vascular events, and this allele increases susceptibility to ischemic stroke, indicating that this allele may have a dual pathogenic and protective role [76, 77].

Ring Finger Protein 213 (RNF213)

In addition to HLA, there has been significant interest in ring finger protein 213 (RNF213) as a single nucleotide variation in the RNF213 gene is strongly associated with MMD onset in both familial and sporadic cases [78]. Mutational analysis of RNF213 in 72 Japanese MMD patients found that 95% of familial MMD cases and 73% of sporadic MMD cases exhibited a founder mutation, p.R4859K, in the gene [19]. Gene ontology analysis demonstrated significant enrichment in the following categories: immune response, response to virus, defense response, inflammatory response, and innate immune response [78]. RNF213 is expressed in high levels in mature lymphocytes, further linking this gene to immune function [79]. To date, only one small study of two European Caucasian siblings with MMS has investigated the relationship between genetic mutations and MMS. This study did not find any association between the RNF213 gene or HLA alleles and MMS. However, it is difficult to assess the validity of these findings given the small sample size.

Animal studies are showing a clear link between RNF213 and the regulation of vasculature. RNF213 is critical to vascular development as *rnf213* knockdown in zebrafish results in irregular formation and abnormal sprouting of craniocervical vessels [20]. However, this finding has not been recapitulated in mice. RNF213 knockout, transgenic, and knock-in mice under basal conditions do not exhibit any changes in cerebrovasculature [80]. Under stressful conditions however, such as hypoxia, a common complication in MMD patients, transgenic mice expressing an orthologue of human RNF213 exhibit impaired compensatory angiogenesis in their cerebral cortex [81], as experienced by MMD patients. Dysfunctional changes in vasculature have been further linked to immunity through *in vitro* studies of RNF213. Induced pluripotent stem cells derived from the vascular endothelial cells of MMD patients with one or two RNF213 risk alleles have lower angiogenic activity compared to unaffected fibroblast donors. In addition, interferon (IFN)- β , an anti-angiogenic cytokine, suppresses angiogenic activity in endothelial cells via the induction of RNF213 [81]. In contrast to these studies, siRNA-mediated knockdown of RNF213 decreases the angiogenic response of endothelial cells, via upregulation of MMP expression, which has deleterious effects on the basement membrane surrounding endothelial cells [78]. Overall, the presence of RNF213 appears to lead to decreased angiogenesis, though conflicting reports exist. Decreased angiogenesis may account for moyamoya effects in the cortex, but does not account for the increase in neovascularizations observed at the base of the brain. It's clear there is a complex relationship between RNF213, inflammation, and angiogenesis in MMD pathology that requires further investigation.

Growth Factors and Cytokines

Several other genes related to cytokines and growth factors have also been associated with MMD. DNA analysis of 40 European MMD patients found two single nucleotide polymorphisms (SNPs) that may be possible genetic risk factors for developing MMD [82]. There was a significant association between a SNP in the promoter region of the PDGF β gene and in the first exon of TGF β 1, which encode a growth factor and a cytokine with immunological relevance, respectively. However, a study by Liu et al. of Japanese and European MMD patients found no association between the TGF β 1 gene and MMD, thus calling into question whether TGF β 1 is truly a susceptibility gene for MMD [83]. Linkage analysis also shows an association between chromosome 3p and MMD. Importantly, chromosome 3p encodes proteins involved in multiple immunological signaling cascades,

including IL-5 receptor alpha (IL5RA) and TGF- β receptor II (TGF β R2) [84]. The VEGF-634G allele has also been linked to pediatric MMD and poor collateral vessel formation after surgery, but no studies to date have replicated this finding [85].

TREATMENT

Unfortunately, there are no therapies available to prevent or reverse the progression of ICA stenosis. Instead, the focus is on reducing the risk of repeated strokes, hemorrhages, or general hypoperfusion of the brain. Antiplatelet treatment, such as aspirin, is commonly utilized for the prevention of stroke. However, evidence for the efficacy of antiplatelet treatment in moyamoya is lacking. In a recent study of MMD patients in Japan, antiplatelet therapy could not prevent recurrent ischemic infarction, possibly due to the fact that the nature of the ischemia is mainly hemodynamic, not embolic [86]. The pathologic changes of the ICA and associated vessels are not prone to platelet adhesion, and therefore antiplatelet therapy may not be effective for preventing ischemic stroke [87]. Surgical intervention to augment intracranial blood flow is currently the only other treatment option, and does improve long-term outcome in patients [87]. Direct bypass involves connecting the superficial temporal artery (STA) from the scalp to a cerebral artery, most commonly the middle cerebral artery (MCA). While improvement in blood flow is observed immediately after surgery, the procedure is technically difficult as the arteries have often shrunk and the vessel walls are fragile [87, 88]. Indirect bypass techniques rely on spontaneous angiogenesis between the cortical surface and donor tissues. The procedure is relatively easy to perform and widely used, though beneficial effects are not immediate and may take several months to develop [89-91].

There are several commonly used indirect bypass procedures: Encephalo-duro-arterio-synangiosis (EDAS) involves making a burr hole in the skull directly below the STA where it is sutured to the dura [92, 93]. This induces the formation of small arterial vessels to the brain without disrupting the integrity of the STA. Encephalo-myo-synangiosis (EMS) uses dissected temporalis muscle from the side of the head, where it is placed onto the surface of the brain through a burr hole in the skull. New vessels can then form between the muscle and brain, thus increasing blood flow [94]. A hybrid method called encephalo-duro-arterio-myo-synangiosis (EDAMS) uses both EDAS and EMS interventions to improve cranial perfusion. Alternatively, other tissue types such as omentum (lining surrounding the abdominal organs) and the frontal pericranial flap [95] or a multiple burr hole technique have been introduced for the development of angiogenesis [87]. Despite relatively few reports, neovascularization with these techniques have been observed [96-99].

While ischemia is the most common sign of moyamoya, hemorrhages occur in approximately 30% of adult patients [100]. Surgical treatment for hemorrhage, as in any patient presenting with bleeding, commonly include intraventricular drainage, craniotomy, and stereotactic aspiration [101]. Interestingly, bypass surgery as mentioned above may also help reduce the rate of recurrent hemorrhagic stroke [102]. Ding et al. state in a meta-analysis of articles reporting on 1050 patients, that revascularization intervention may be an optimal strategy to reduce hemorrhage in moyamoya patients [102]. Since decreased basal perfusion appears to be associated with recurrent bleeding in moyamoya patients, rectifying the

perfusion abnormality may prove beneficial [101]. While these treatment options can improve patient survival, a better understanding of moyamoya pathogenesis is needed to find treatment options that are less invasive and possibly reverse ICA stenosis.

Case Scenarios

It is vital to understand these cellular and biochemical changes in the context of clinical case scenarios. These cases highlight the variety of presenting symptoms, vasculopathy severity, and treatment options for people suffering from moyamoya.

Case 1: Hemorrhagic Presentation

Figure 1. Non-contrast CT scan shows left caudate intracerebral hemorrhage (A) and intraventricular hemorrhage (B). Right (C) and left (D) AP views on digital subtraction angiography demonstrate bilateral moyamoya with occlusion of the supraclinoid internal carotid arteries (ICA; arrow) and robust lenticulostriate collateral formation (arrowhead).

A 54 year-old female with a known history of MMS and prior ischemic strokes, intraventricular hemorrhage, and ventriculoperitoneal (VP) shunting presented to our institution for the first time after becoming unresponsive in a witnessed incident. She was intubated on-scene, and brought to the emergency department, where her neurological exam was: awake, intubated, opens eyes to voice, localizing bilaterally, with some notable weakness of the right side. Non-contrast head CT showed a unilateral left basal ganglia intracerebral hemorrhage (ICH; Score 2) with intraventricular hemorrhage (IVH; Figure 1A and 1B). In addition, she was found to have a VP shunt infection. Ventriculostomy was placed and the VP shunt was removed. Cerebral angiography showed bilateral Suzuki stage VI MMS (Figure 1C and 1D). After 14 days of antibiotics and CSF drainage, her ventriculostomy was converted back to a VP shunt once CSF cultures were negative. This case illustrates not only a hemorrhagic presentation, but also some chronic complications of

moyamoya. The patient had previous disability related to multiple prior infarcts and hemorrhages, and she suffered a known complication of ICH/IVH; she had a VP shunt secondary to hydrocephalus caused by the ICH/IVH. Furthermore, she presented with a concomitant CSF infection, a known risk of VP shunts. Thus, this case demonstrates the true complexity of long-term management of moyamoya patients.

Case 2: Ischemic Presentation

A 36 year-old female with a history of migraine headaches, hypertension, and recent urinary tract infection presented with acute left arm weakness and numbness in the setting of a headache. Her NIH Stroke Scale on presentation was 3, and MRI demonstrated small scattered ischemic infarcts in the right watershed region (Figure 2A). Digital subtraction angiography (DSA) demonstrated bilateral Suzuki stage III MMS (Figures 2B and 2C). The patient underwent indirect bypass with EDAS and follow-up DSA 14 months later demonstrated robust collateral formation (Figures 2D-2G). This case highlights some vital concepts in moyamoya. First, not all strokes related to moyamoya are devastating and large; some are particularly small and focused along the cerebral watershed, a border zone between the tissues supplied by the anterior, posterior and middle cerebral arteries. As such, moyamoya can mimic complex migraine headaches. Second, as shown on the follow-up angiograms, the brain is ‘primed’ for neovascularization to feed the vascular requirements for adequate perfusion. Even with indirect bypass techniques, robust moyamoya collaterals still form.

Figure 2. Diffusion-weighted MRI (A) shows small punctate infarcts along the ACA-MCA watershed (arrow). Right (B) and left (C) internal carotid artery injections on AP view demonstrate bilateral moyamoya. The patient underwent successful indirect bypass via the superficial temporal artery and middle meningeal artery with robust collateralization seen on the right [(D) unsubtracted and (E) subtracted] and left [(F) unsubtracted and (G) subtracted].

ANIMAL MODELS

One of the best ways to examine mechanisms that lead to the pathogenesis or progression of disease is with the use of experimental animal models. Animal models can undergo similar radiologic imaging currently used to diagnose moyamoya and can be used to study the effects of inflammation on blood vessel function. Furthermore, these models can be used to study the effects of moyamoya on cognition, an increasingly recognized chronic impairment in moyamoya patients. Although the etiology of MMD remains unknown, attempts to establish animal models are underway. Since chronic inflammation is thought to be a factor, studies which induce immunological reactions in the blood vessels of animals have been performed [103-105]. All of these studies resulted in alterations to the terminal ICA, including duplication of the elastic lamina, degeneration of media, and intimal thickening, as observed in moyamoya. However, the changes were minimal and were not sufficient to induce arterial stenosis, the major component of the disorder.

Figure 3. Images of Di I perfused brains from control (A) and ICAS (B) treated mice show decreased vessel diameter at the Circle of Willis 28 days after ICAS surgery. The internal carotid artery (ICA) bifurcates into the middle cerebral artery (MCA) and anterior cerebral artery (ACA).

As mentioned above, recent genome-wide and locus-specific association studies identified RNF213 as an important MMD susceptibility gene. A polymorphism in this gene was identified in 95% of familial and 79% of sporadic Japanese MMD patients [19]. Therefore, genetically engineered mice lacking RNF213 were generated by homologous recombination [106]. The authors performed magnetic resonance angiography (MRA), examined the anatomy of the Circle of Willis, and sectioned and stained the blood vessels to examine structural differences between the RNF213 knockout (RNF213KO) mice and wild-type littermate controls. Overall, there were no significant differences in the MRA, anatomy, or vascular wall thickness between groups out to 64 weeks of age. The authors report the RNF213KOs did not sufficiently induce MMD and recommend additional insults (inflammation, autoimmune response, ischemia) may be necessary for the development of MMD [106]. To address this question, Ito et al. performed transient MCA occlusion (tMCAO) on RNF213KO mice. Unfortunately, they did not find any differences in infarct volume, edema, or vascular density compared to wild-type controls. Interestingly, they did

report enhanced hind-limb angiogenesis and improved ambulation in the RNF213KO mice following hind-limb ischemia [107]. While RNF213 may be involved in the development of peripheral vascular networks following injury, its role in the vasculature of the brain remains unclear. To complicate matters, Sato-Maeda et al. report an upregulation of RNF213 in neurons following tMCAO. The increased expression of RNF213 mRNA co-localized with TUNEL-positive (apoptotic) neurons within the ischemic penumbra, suggesting RNF213 may be involved in either cell death or attempted survival following injury [108]. Further investigation is required to clarify the role of RNF213 in the pathophysiology of MMD.

While MMD is thought to have a genetic component, MMS is sporadic and associated with other well characterized co-morbidities. To examine the pathogenesis of MMS, we developed the ICA stenosis (ICAS) surgical procedure in which a micro-coil was applied unilaterally to induce hypoperfusion in mice [109]. We report a significant decrease in the diameter of the distal ICA (Figure 3), as well as a decreased number of cortical anastomoses in the watershed region, both consistent with MMS. While the pathology observed after 28 days is consistent with an early Suzuki stage and more extensive evaluation is needed, this methodology could provide a key tool for studying MMS in the laboratory. Specifically, this model can be employed in a variety of co-morbid animal models to investigate the effect disorders may have on MMS development and progression.

CONCLUSION

In conclusion, moyamoya is an increasingly recognized cause of stroke in both children and adults. As more varied populations present with moyamoya across the world, there is a growing need to delineate syndrome from disease, as factors that influence vasculopathy development may differ between the two. Inflammation could be a key player in the development and progression of moyamoya pathology, though additional studies are needed to determine the exact role of the immune system in both MMD and MMS. The use of newly developed animal models are critical to our understanding of these pathologies and for the possible development of new treatment strategies. While revascularization interventions provide temporary benefit, extensive epidemiological, genetic and co-morbid disorder research will need to be undertaken to fully understand this phenomenon and how best to treat those patients that suffer from it.

Chapter 83

THE COMBINED USE OF tDCS AND OTHER REHABILITATION TECHNIQUES TO IMPROVE UPPER LIMB MOTOR FUNCTION AFTER STROKE

C. Chisari, G. Sgherri, G. Lamola and B. Rossi

Unit of Neurorehabilitation, University Hospital of Pisa, Italy

ABSTRACT

Transcranial Direct Current Stimulation (tDCS) has recently gained a lot of attention as a tool to modulate neuronal plasticity influencing motor learning processes and functional recovery after stroke (Schlaug & Renga 2008; Chisari et al. 2014). The main conceptual target is to use tDCS for normalizing imbalanced inter-hemispheric inhibition, increasing excitability of perilesional intact regions of the affected hemisphere with anodal stimulation and/or decreasing excitability of the contralesional hemisphere with cathodal stimulation (Celnik et al. 2009; Fregni et al. 2005; Hummel et al. 2005; Hummel & Cohen 2005; Hummel et al. 2006). First evidences demonstrated transient improvement of upper limb motor function after a single session of tDCS and some studies have suggested potentially cumulative effect of multiple sessions of tDCS in improving motor learning in healthy subjects and hand motor recovery in patients with stroke (Boggio et al. 2007; Reis et al. 2009). These findings allow to support the hypothesis that combining multi-sessions tDCS protocol with other upper limb rehabilitative techniques which use principles of motor learning in clinical settings could be optimal to improve upper limb motor recovery after stroke (Wessel et al. 2015; Nair et al. 2008).

At this purpose we overviewed studies in which a combined upper limb rehabilitative therapy including tDCS was administered to subacute or chronic stroke patients. Different treatments were associated with tDCS such as virtual reality-based therapy (VRT), robot assisted arm training (AT), constraint induced therapy (CIMT), or occupational therapy (OT). First evidences revealed that tDCS sessions can be administered simultaneously to conventional therapy sessions, and the mean tDCS treatment duration was about 10-15 sessions for 2-3 weeks. Most of these studies showed significant effects for experimental treatment groups versus control groups, evaluated with different clinical scales for upper limb motor function. All studies used functional scales to explore upper limb motor improvement, but e.g., Bolognini et al. (2011) also

showed a neurophysiological correlate to identify reduction in inter-hemispheric inhibition probably mostly due of tDCS effects. Particularly effective was the association between tDCS and OT or CIMT (Nair et al. 2008; Lindberg et al. 2012; Bolognini et al. 2011). Conversely other types of combined trials showed no significant or only preliminary results in upper limb outcome measures, probably due to a very small sample size.

In this overview we conclude that tDCS can be considered an important tool to maximize the effects of traditional therapies for upper limb motor recovery, modulating the plasticity-dependent processes after stroke (Wessel et al. 2010). However it will be useful to clarify the timing and duration of tDCS administration protocols and how these parameters influence other therapies effects, in order to identify a useful combined upper limb rehabilitation strategy for stroke patients.

INTRODUCTION

Upper limb motor impairment is common in patients after stroke. It causes an important restriction in daily activities and strongly impacts on quality of life (Carod Artal E et al. 2009; Kwon SU et al. 2000). Currently stroke rehabilitation strategies are developed on increasing scientific and clinical evidences based on neural remodeling after brain damage and neuroplasticity mechanisms (Kleim et al. 2008).

It is now widely known that neuroplasticity is the property of the nervous central system to modify and rearrange neural connections following injury or environmental changes and it is not only an occasional state but the normal ongoing state of the nervous system throughout the life span (Cramer et al. 2011; Chisari et al. 2014).

Combined Therapies for Upper Limb Motor Recovery

Transcranial direct current stimulation (tDCS) represents the noninvasive version of direct current application to the scalp and it modulates cortical activity by constantly applying weak electrical current over time to increase or decrease cortical excitability (Nitsche et al. 2008). In stroke rehabilitation this means that anodal tDCS (A-tDCS) may be employed over the affected hemisphere to improve the response of that hemisphere to training protocols, or on the other side, cathodal stimulation (C-tDCS) may be used to inhibit the unaffected hemisphere in order to reduce trans-hemispheric inhibition (Hummel et al. 2005). In addition tDCS can be used applying bihemispheric stimulation that contemporary modulate the unaffected and affected motor cortex (Dual-tDCS) (Nitsche et al. 2003; Lindberg et al. 2010). About this a great consideration should be given to the placement of the electrodes and the focality of tDCS interventions. Different electrode configurations may result in different patterns of current spreading over the scalp and consequently on the cortex. It is feasible that the typical “reference” position over the supraorbital region may produce undesired stimulation in non-target regions, thus newer monopolar stimulation montages attempt to avoid this problem (DaSilva et al. 2011). While substantial work is under way to model the fields induced by these different montages, clear behavioral or physiological data is lacking on the differences between these approaches. A lot of studies explored tDCS effects on healthy subjects and the most commonly studied brain area is the left M1. For M1 modulation

active electrode is placed over the representative field of the right hand, whereas the reference electrode is generally placed on the contralateral supraorbital region (Nitsche et al. 2008). Lots of these studies demonstrated that tDCS applied over M1 influences cortical connectivity with more evident results (measured by EEG or fMRI) during voluntary hand movements than during rest (Polania et al. 2011; 2012). In particular Polania et al. (2011) showed an increased synchronization in alpha and lower frequency bands in frontal and parieto-occipital regions, and in the high gamma frequency band in motor related regions during voluntary hand movements and with fewer changes in during rest. Another work demonstrated that anodal tDCS over left M1 during rest only increased the power density of low frequency oscillations (theta, alpha) (Pellicciari et al. 2013). These results suggest that major changes in brain activity associated with tDCS are augmented by its combination with performing an active behavioral task (Fritsch et al. 2010). All these evidences allowed to think that coupling an hand task or a different treatment for upper limb with tDCS in stroke patients could have a synergic effect on motor recovery. So far tDCS has been used as a treatment to enhance motor recovery after stroke, but it has been mostly examined without or independently of a specific rehabilitation treatment and its effects have been evaluated in term of functional improvement with neurophysiological measures (Bolognini et al. 2014). Another important aspect of tDCS administration is treatment duration: it is not clear until now if a multisession protocol leads to longer lasting and more evident effect compared to single sessions of brain stimulation. Single sessions of tDCS showed only short-lasting and variable effects on cortical excitability and performance both healthy subjects and stroke patients (Nitsche et al. 2008). Recent studies reported positive effects of tDCS treatments on activities of daily living (ADL) and on upper limb motor function. They showed evidence in favor of tDCS short-term effects compared with controls at the end of the intervention phase (in terms of Fugl-Meyer upper limb score), but not at three months follow-up (Elsner et al. 2013). Effects of combined treatments were also analyzed in other studies in which an upper limb (UL) rehabilitation treatment was associated with tDCS sessions (Tedesco Triccas et al. 2015). Wide variability in protocols, patients' upper limb motor impairment and different timing of treatment administration made difficult to understand the results. In the following text we cited studies in which a combination of tDCS and upper limb treatment was applied in stroke patients. First of all, in all studies chronic stroke patients were enrolled, except for one paper (Lee and Chun 2013) in which the intervention was applied in subacute post-stroke phase. In addition limited details were reported about stroke location and lesion size. However the majority of these studies declared that participants had moderate UL impairment. A wide variability has been showed in tDCS protocols even for stimulation time, current intensity, electrode size, and type of stimulation. Bihemispheric stimulation was applied in two of these studies (Bolognini et al. 2011; and Lindberg et al. 2012), anodal stimulation in one (Viana et al. 2014), anodal plus cathodal stimulation without sham in another one (Ochi et al. 2013), and cathodal stimulation protocol in the last two (Lee et al. 2014; Nair et al. 2011).

tDCS + Constraint Induced Movement Therapy

Constraint-induced movement therapy (CIMT) is a stroke rehabilitation approach that involves the forced use of the affected arm by restraining the unaffected arm (Corbetta et al. 2010). Bolognini et al. (2011) conducted a randomized control study in which 14 chronic stroke patients with a moderate to severe hemiparesis (Upper Extremity Fugl-Meyer, UE-FM, mean score 26) were randomized between a combined CIMT and bihemispheric tDCS group

and a sham group. Each subject underwent a 14-day CIMT up to 4 hours per day administered by a trained therapist. They had to wear a resting splint secured in a sling, which hindered hand and finger movements and they had to complete 9 different shaping tasks. Bihemispheric tDCS was applied during rehabilitation sessions to study group and stimulation time was about 40 minutes, while control group received sham tDCS (that consisted in a 30 sec of stimulation) and CIMT. They collected functional outcome measures at baseline, day 1, day 5, at the end of the treatment and at 2 and 4 weeks follow up. They used qualitative scales as Jebsen Hand Function Test (JHFT), Motor Activity Log Rating Scale (MAL) and quantitative evaluations as Fugl-Meyer (FM), Handgrip Strength (HS) for upper limb activity. They also evaluated neurophysiological parameters for cortical excitability assessment such as motor evoked potential (MEP) and transcallosal inhibition (TI) in both cortices. As it concern motor function the treated group showed an improvement in UE-FG score and HS at the end of the treatment that was absent in sham group. Qualitative scales didn't show significant difference between the two groups. Active group also showed increased mean peak-to-peak amplitude of MEPs after the treatment, not evident in sham group. Changes in cortical excitability were correlated to motor improvement. A positive correlation was found in MEPs amplitude of the affected hemisphere and FM score. Conversely negative correlations were found between intact-to-damaged TI and the FM score and the JHFT. They demonstrated that bihemispheric tDCS increased the effects on upper limb motor function induced by CIMT as assessed with JHFT, HS and FM. They concluded that tDCS bring about a more favourable interhemispheric balance. This study described subjects and treatment characteristics in details and upper limb motor impairment with multiple evaluation scales were analyzed interpreting results with a neurophysiological correlation.

tDCS + Virtual Reality Therapy

Virtual Reality Therapy (VRT) is a computer-based technology that permits the interaction with a multisensory simulated environment and allows to receive a real-time feedback on motor performance. Exercises in VRT have the potential to apply relevant concepts of neuroplasticity (Langhorne et al. 2009). Viana et al. (2014) conducted a RCT on chronic stroke patients randomized in two groups: one for a combined 5 weeks treatment composed by virtual reality therapy (Wii gaming System) and anodal tDCS, and control group with VRT and sham tDCS. They enrolled 20 patients with mean age of 56 ± 12.2 years with unilateral ischemic (except 1 hemorrhagic) stroke within the previous six months. No data have been cited regarding lesion location. Baseline assessment has been conducted with Mini Mental State Examination (MMSE) for cognitive profile and with FM, Wolf Motor Function Test (WMFT), Modified Ashworth Scale (MAS), Grip strength for quantitative motor assessment and Stroke Specific Quality of Life scale (SSQoL) as qualitative tests. Patients were homogeneous for clinical and functional characteristics and they were included only if they were able to hold Wii controller. This type of treatment determined a straight selection of patients because they didn't have to present cognitive impairment, with a mild-to-moderate upper limb motor impairment. Treatment consisted in 3 times for 5 weeks, one hour per session of Wii console games, 3 games with different tasks associated for experimental group with anodal tDCS sessions. It was not declared if stimulation occurred during or far from the Wii performance. Outcome measures were collected at the end of treatment. Both groups experienced after treatment similar improvement underlined through changes in the FM-UL

and WMFT scores, with no significant difference between them. Even though the hypothesis of this study was to associated the previous demonstrated beneficial effects of 15 hours VRT on upper limb motor rehabilitation (in particular on ADL) with the beneficial of tDCS treatment, this combined treatment didn't demonstrate an increased positive effect on UL motor recovery. However they showed that only experimental group revealed decrease tonus of the wrist flexor muscles, and this evidence was supported by other tDCS study (Wu et al. 2012). A different associated therapy was tested in one of the 3 study groups conducted by Lee et al. in 2014. In this case they tested subacute patients (within 1 month after stroke). Subjects were randomly assigned to this experimental group who received combined therapy with cathodal tDCS administered during 15 VRT sessions (30 min/d, 5 times/wk for 3 weeks) or to one of the other study groups. Cathodal tDCS was performed placing the electrode on unaffected hand motor area with an intensity of 2 mA. Virtual reality system used for UL rehabilitation consisted in a monitor, video camera and computer that recognized the system's gloves and virtual objects, able to recognize the patient's movement and position and transfer subjects into the virtual space. Each patient, viewing him/herself into the virtual scene, must performed three different reaching and trajectory programs using the affected arm. Twenty patients tested this type of treatment and results were compared with other two study groups which experimented tDCS and occupational therapy or only VRT. Patients in three groups were homogeneous for gender and age (mean 60+/-13) and also for lesion type (hemorrhagic/ischemic) and location (cortical/subcortical). They were tested before and after treatment and all groups demonstrated a significant improvement in clinical scales at the second assessment. However combined treatment with tDCS and VRT group showed significant improvement in Motor Function test and FM compared with other groups and the latest was significantly higher. In conclusion these results supported a synergic effect of two different treatments on motor recovery after stroke. In particular patients enrolled in this study had no severe UL motor impairment and MEP were present. The combination of brain stimulation using tDCS and peripheral arm training using VRT could provide additional benefits to the training of UL recovery after stroke over those achieved with either intervention alone. This paper differs from the others because authors described an early treatment in subacute stroke patients and it will have a good impact on motor recovery. In addition all subjects received conventional rehabilitation including physical, occupational and cognitive therapy with the same intensity and time, but it is a potential risk of bias that could implement rehabilitation effects.

tDCS + Robot Assisted Arm Training

Robotic devices allow users to participate in interactive training and motor relearning via high-intensity, repetitive, and frequent tasks (Peter et al. 2011; Basteris et al. 2014) and were recently widely used in rehabilitation trainings. This kind of combined treatment was tested by Ochi et al. (2013) on 18 chronic stroke patients. All patients received two interventions, comprising either anodal tDCS to the affected hemisphere with Robot Assisted Arm Training (AT) or a cathodal tDCS to the unaffected hemisphere with AT for 5 days in a cross over manner. The two interventions were separated by a 2 days period. Patients had a long-term, moderate to severe motor impairment of an upper limb from a first stroke that had occurred over 6 months before. In this case 11 patients experimented an hemorrhagic stroke and 7 an ischemic ones. Upper limb treatment was performed with the Bi-Manu-Track robotic arm trainer, which permitted a mirror-like practice of two movements cycles: forearm pro-

supination and wrist flexion-extension. Patient grasped with both hands a handle with a strap holding the paretic hand in place. Within one session subjects practiced 500 forearm cycles and 500 wrist cycles for a total of 1000 cycles in 2 different modalities: passive-passive in which both arm were moved by the robot and active-passive with the unaffected arm driving by the affected side. Direct current stimulation was delivered at 1 mA for the first 10 minutes during AT. Clinical evaluations were performed before and after the two training sessions with FM-UL, MAS and MAL. The final analysis showed that there were small but significant improvement effects on FM-UL and MAS in both trainings, but not in MAL. In particular there were no significant effects comparing the first and the second stimulation period, and only the cathodal stimulation and AT was associated with an improvement in MAS for fingers. This evidence supported the previous results even in chronic patients of anodal tDCS and AT combined treatment showed by Hesse et al. (2011) on subacute stroke ones, but also added similar results for cathodal stimulation of the unaffected hemisphere. However in this case there wasn't a sham group to compare the no-treatment effect and patients enrolled were very heterogeneous even for type of lesions.

tDCS + Occupational Therapy

This type of combined treatment was tested, compared with a sham treatment, on fourteen right handed stroke patients by Nair et al. (2011). The experimental group contained 5 patients with predominantly cortical lesions including the immediate underlying subcortical regions and 2 with deep white matter/striato-capsular regions. In the sham group 4 subjects had a predominantly cortical lesion and 3 white matter/striato-capsular lesions. Subjects, aged between 20 and 76 years, were randomized between a 5 days cathodal tDCS and OT group and a sham tDCS and OT group. Stimulation consisted in 1 mA intensity current applied during the first 30 minutes of one daily hour of occupational therapy, focusing on proprioceptive neuromuscular facilitation techniques. In this case patients were evaluated at baseline with Range-of-motion (ROM) measure for shoulder abduction, elbow and wrist extension and with FM-UL and these measures were repeated after one week to the end of treatment. They also employed a fMRI evaluation in which has been request to the patient to performed one of 2 motor tasks that could be: a full wrist extension and flexion or a full elbow flexion and extension up to the maximum excursion (if the patient was not able to perform the first). In this case all subjects had a moderate to severe upper extremity impairment and patients in experimental group showed slight differences to the disadvantage in terms of mean age, time to stroke and lesion size (even if these differences were not significant). However this study showed that the combined therapy enhanced UL motor function in chronic stroke patients with moderate to severe motor impairment, more than similarly intense protocol of sham tDCS and OT. These results were supported by ROM and FM-UL outcome measures that were significantly greater in experimental group after the treatment. In addition fMRI was used to analyze changes in activation in precentral gyrus region, demonstrated that cathodal tDCS applied to the contralesional hemisphere resulted in a reduced activation level, presumable referring to a decrease of the abnormal excitability levels in that hemisphere. This evidence was supported by the finding of an inverse correlation between changes in contralesional activation and a positive progression in the FM-UL score. A variant of this combined treatment was used by Lindberg et al. (2012), that tested a double 5 sessions treatment compared with a sham treatment on 10 chronic stroke patients. They used a combination of 30 minutes bihemispheric tDCS during one hour of upper limb

therapy. Upper limb therapy consisted in a combination of physical therapy (PT) and OT techniques, including functional motor tasks of the affected arm and hand to promote coordination of movement, goal-directed strategy and sensorimotor integration. Therapists administered the first 5 days session and after a period of 2-29 day a second session of 5 days rehabilitation. Patients enrolled, mean age 50,3 $\pm$ 15,2, experimented first ischemic event and they were heterogeneous for lesion size and location. WMFT and FM-UL assessment were done at baseline for each 5 days-session and after the first and the second rehabilitation period. Results reported that changes were greater during the first intervention than the second for both outcome measures, and mean improvement in the experiment group was substantially greater compared with the sham. However results obtained after the second treatment period were lower than those observed during the first. It's difficult to compare this kind of rehabilitation protocol with the others cited below, because it was administered in two different times with a variable interval between subjects. They also enrolled a very small and heterogeneous sample size that could confound results.

Comments

From a general point of view, these studies demonstrated that multisession tDCS protocol could be safety and easily applied even simultaneously combined with other rehabilitative approaches for stroke patients. However systematic reviews and meta-analyses showed that multiple sessions of tDCS regimens combined with UL rehabilitation had a small and no-significant effects on upper limb impairment (Tedesco Triccas et al. 2015). Actually tDCS has not yet been applied in clinical practice as a rehabilitative treatment and as it showed in previous paragraphs, there is still a wide variability in tDCS protocols applied in stroke patients. Therefore it is unclear what kind of UL rehabilitation treatment can be synergic, useful or non-influent in association with a central stimulation intervention. Probably these small evidences can be due to a lot of difference, not only in protocols used but also in patients' clinical characteristics, lesion type and grade of upper limb motor impairment. However, given this variability, a "one size fits all" approach is not to be considered optimal for stroke rehabilitation (Gary et al. 2015). Accordingly, there is a great interest in identifying appropriate markers in order to obtain a specific targeted rehabilitative treatment that combines central and peripheral stimulation.

Chapter 84

DOES ANOSOGNOSIA AFFECT THE SHORT-TERM GOALS ACHIEVEMENT IN MEDICAL REHABILITATION FOR PATIENTS WITH ACUTE ISCHEMIC STROKE?

V. N. Grigoryeva and T. A. Sorokina
Nizhniy Novgorod State Medical Academy, Russia

ABSTRACT

Insufficiency of self-awareness for neurological deficits may negatively affect the functional outcomes in medical rehabilitation due to the decreased engagement of the patients in the rehabilitation process [1-4]. However, its relationships with rehabilitation goals attainment in the patients with acute ischemic stroke (IS) have not yet been clarified.

PURPOSE

To evaluate the impact of anosognosia on the short-term functional rehabilitation goals achievement in the acute ischemic stroke patients.

METHODS

We examined 57 patients (36 males, 21 females, mean age $64,8 \pm 9,2$ years) in the beginning of acute period of ischemic stroke (mean time since IS = $4,8 \pm 1,1$ days) and then 2 weeks later.

Inclusion criteria were: acute period of ischemic stroke; neurological and cognitive deficit interfering with function. Patients were excluded if they had severe cognitive

impairment (dementia), aphasia or concomitant illness that prevented the understanding of instructions and active participation in rehabilitation process.

The assessment consisted of clinical neurological examination, neurovisualisation (CT/MRI), use of Frontal Assessment Battery (FAB) [5] and several assessment methods aimed at detecting of anosognosia. We used our own method of evaluation of unawareness for motor and cognitive abilities in brain damaged patients (EUMCA) as well as Russian version of Dysexecutive Questionnaire (DEX) of the Behavioural Assessment of the Dysexecutive Syndrome (Wilson B.A. et al, 1996; BADS Russian Translation 2009 by Pearson. All rights reserved) and Anosognosia Score for Hemiplegia [6,7].

EUMCA comprises two parts, one to assess inadequacy of self-rating of motor abilities (MA), and second to assess inadequacy of self-rating of cognitive abilities (CA). Each part is based on a comparison of predicted and actual performance of a set of simple tasks in motor and cognitive areas, respectively. Perception of self-capabilities was measured using two questionnaires. Each of them included 10 questions for self-appraisal of daily life activities. Actual performance was assessed using two objective rating subscales for the same tasks that were asked about in the questionnaires. The cognitive tasks were addressed to executive, visual-spatial and memory functions. We have previously shown that both questionnaires and both objective rating subscales had acceptable psychometric characteristics according to Rasch analysis. This allowed to measure unawareness for motor or cognitive abilities as the discrepancies between self- anticipated and observed performance of motor or cognitive tasks. Discrepancy scores both for motor tasks and cognitive tasks had a normal distribution so they were converted into standardized scores (z-scores) on the basis of normative data. The standardized scales for evaluation of unawareness for motor abilities (UMA) and cognitive abilities (UCA) were created. The criterial validity of the proposed scales has been verified by applying of DEX at the previous stages of work. The discrepancy score that exceeded the average value on a standardized scale more than for two Z- scores was taken as a criterion of pathological overestimation of motor abilities ("anosognosia for motor deficit") and as a criterion of pathological overestimation of cognitive abilities ("anosognosia for cognitive deficit"), depending on the used set of tasks.

The patients underwent a 2-week multidisciplinary early task-oriented rehabilitation. In case of anosognosia the rehabilitative specialists purposefully captured the patient's attention to his/her neurological deficit to increase the awareness of this deficit and to involve the patient in the rehabilitation process. Individual short-term rehabilitation goals in the domains of impairment, mobility and activities of daily living were formulated for each patient and agreed with him/her at the initial team meeting. In this study we analyzed the degree of achievement of goals only in the domains of mobility and daily activity ("function" goals) because the regress of impairment to a large degree occurs spontaneously in the acute period of stroke. The achievement of functional goals was scored prior to the rehabilitation in accordance with Goal Attainment Scaling [8]. There was no hierarchy of goals, and all goals were given a weight of «1». Indicators of improvement, or lack of it were identified in behavioral terms. The expected level of outcome was specified for each selected goal and a primary value of "0" was assigned to it. Baseline primary scores for each goal were rated as "-2". Primary scores for "somewhat less than" expected levels of each outcome were rated as "-1", where scores "0" and above implies the full goal achievement.

Functional improvement was measured in 2 weeks using Goal Attainment Scaling as an indicator of success. Rating of individual goal attainment was undertaken at follow-up in 12

days according to the initial specifications for outcome levels. The aggregated composite T-score of each participant's goals attainment was calculated as recommended by S.Gauggel and V.Hoop, 2004 [9]. Median achieved T-scores were 50. Scores above 50 indicated a better outcome than expected; scores below 50 indicated a worse-than-expected outcome.

The degree of final goal attainment of the patients was graded as a complete goals achievement (CA), incomplete achievement (IA) and lack of achievement (LA). Exceeding of the planned goals was also evaluated as "CA". The absolute lack of achievement of the patient's selected goals was diagnosed if the final aggregated T score corresponded to the baseline "-2" level for each target, i.e., to the baseline level of the patient's abilities.

Descriptive statistics were used to summarize patient's characteristics which were described as frequency and percentage, median and range. Groups were compared by Fisher's exact test. To assess the baseline UMA scores and UCA scores in CA, IA, LA patients, the nonparametric test of Kruskal-Wallis was used. The difference between two groups were analysed with U Mann-Whitney test. Correlation between variants was assessed with the use of Spearman's rank correlation coefficients. A value of $p < 0.05$ was considered as statistically significant.

RESULTS

The patients were divided into three groups in accordance with the results of EUMCA, DEX and Anosognosia Score for Hemiplegia: group 1 (without any anosognosia, 15 patients), group 2 (anosognosia for cognitive deficit only, 24 patients) and group 3 (anosognosia for both cognitive and motor deficit, 18 patients). Pathological overestimation for motor abilities coexisted with pathological overestimation for cognitive abilities in all cases. In other words, there were no patients with "isolated" anosognosia for motor deficit, i.e., without coexistence with anosognosia for cognitive problems.

The patients in the third group had right-sided hemispheric ischemic stroke (16/18 or 89%) more often than the patients in the first group (7/15 or 47%), $p = 0,048$, and in the second group (16/24 or 67%) $p = 0,004$. Involvement of a right parietal lobe was also more frequent in the third group (13/18 or 72%) than in the first (2/15 or 13%), $p = 0,006$, and in the second group (8/24 or 33%), $p = 0,0003$. At the same time, there were differences between the 1, 2 and 3 groups in FAB results ($F = 23,95$, $p = 0,0000001$). FAB score in patients without any anosognosia ($15,4 \pm 1,7$) was higher than in the patients with cognitive anosognosia only ($11,1 \pm 2,8$), $p = 0,000005$ and in the patients with anosognosia for both cognitive and motor deficit ($9,1 \pm 3,0$), $p = 0,03$. The patients with "isolated" cognitive anosognosia had the higher FAB score in compare with the patients with anosognosia for both cognitive and motor deficit. In the whole group of observed patients FAB score negatively correlated with UCA ($r = -0,53$, $p < 0,05$) and with UMA ($r = -0,40$, $p < 0,05$). In other words. the better the function of the frontal lobes, the less overestimation of cognitive and motor abilities in the acute stroke patients.

CA of the individual functional rehabilitation goals was found in 18 patients on the final evaluation, while IA and LA were identified in 24 and in 15 patients, respectively. The proportion of patients without any progress in achieving the goals toward which one has worked, was statistically higher in the patients with baseline anosognosia for both cognitive

and motor deficit, i.e., in the third group (10/18 or 55,6%) than in the first group 1 (2/ 15 or 13,3%) and second group (3 /24 or 12,5%), $p = 0,006$ and $0,001$, respectively. There were no statistically significant differences in the frequencies of IA and CA between the first and the second groups.

The assessment of the baseline UMA scores in CA, IA, LA patients demonstrated statistically significant interaction between the baseline unawareness for motor abilities and the degree of the goals achievement ($F = 3,96$, $p = 0,025$). In patients who finally did not achieve the rehabilitation goals, the baseline mean UMA Z score ($+2,8$ [$+1,0$; $+3,4$]) indicated the pathological overestimation of motor abilities (“anosognosia for motor deficit”). In the patients who completely or partially achieved the rehabilitation goals, the baseline median UMA Z scores were within the normative range. The mean baseline UMA Z-score was higher in LA patients in compare with the IA patients ($+1,0$ [$-0,3$; $+2,0$]), $p = 0,031$, and the CA patients ($+1,2$ [$-0,2$; $2,0$]), $p = 0,06$.

Similarly, there were differences in the initial UCA scores in the CA, IA and LA patients ($F = 5,67$, $p = 0,006$). The baseline mean UCA Z score ($+3,1$ [$2,4$; $4,6$]) in the patients with lack of goals attainment designated the pathological overestimation of cognitive abilities (“anosognosia for cognitive deficit”). It was higher in the LA patients than in the IA patients ($+2,4$ [$+1,0$; $+2,6$]), $p = 0,002$, and that in the CA patients ($+2,4$ [$+1,4$; $+2,8$]), $p = 0,06$, respectively.

DISCUSSION

Anosognosia for both motor and cognitive deficit in our study was associated not only with the right parietal lobe involvement but also with the worse frontal lobe function. This assumption is supported by correlations between FAB scores, UCA and UMA scores that were found in our study. It is consistent with the data of A.De Carolis et al. (2015), who demonstrated the association between anosognosia and general cognitive deficit in nondemential patients. These authors concluded that anosognosia depends on the dysfunction of an extensive neural network including the frontal lobe structures [10].

The large number of patients (15/57 or 26%) in our study did not reach the intended rehabilitation functional goals at all. This can be explained by the fact that we evaluated progress only in the domains of mobility and daily activity, but not in impairment sphere. If we assessed also the goals in the domain of impairment, the results would be obviously better. The lack of goals attainment was observed most often in the patients with anosognosia for both cognitive and motor deficit than in patients without anosognosia or with anosognosia for cognitive deficit only. This fact agrees with studies indicated that the patients with anosognosia for hemiparesis do not feel the need to participate in rehabilitation and so have poorer functional outcomes [11-13].

The impact of anosognosia for cognitive deficit on the effectiveness of rehabilitation of stroke patients is less known. H.Boosman et al. (2014) found that overestimation of memory functioning may be present in stroke patients with a good functional outcomes [14]. However, the effect of unawareness of other cognitive problems on the results of medical rehabilitation has not been studied. The fact that the patients without anosognosia and with isolated cognitive anosognosia in our study did not differ in the frequencies of the lack of

rehabilitation goals achievement, complete goals achievement and incomplete achievement are consistent with data of H.Boosman et al. [14]. Our results suggest little influence of overestimation of cognitive deficit on the goals attainment in rehabilitation of patients without dementia.

However the baseline UCA scores in our study were higher in the patients who finally did not achieve the functional rehabilitation goals. Seemingly, it implies that pathological overestimation for cognitive abilities prevents the achievement of short term functional rehabilitation goals in the acute stage of ischemic stroke.

But there is no contradiction with the above results. The higher baseline UCA scores in the patients who failed to achieve the rehabilitation goals most likely were most likely due to the fact that part of the patients with pathological overestimation of cognitive abilities had also the pathological overestimation of motor deficit, which, in turn, was associated with worse functional outcomes. The negative influence of overestimation for both cognitive and motor abilities on the goals achievement may be mediated by frontal lobe dysfunction, which on the one hand predisposes to anosognosia, and, on the other hand, impairs the purposeful activity. This assumption is supported by correlations between FAB scores, UCA and UMA scores that were found in this study.

Further studies are needed to clarify whether the use of special techniques facilitating the regress of anosognosia (such as video-based self-analysis of errors) may improve the results of rehabilitation of the patients, pathologically overestimated their abilities.

CONCLUSION

The coexistence of pathological overestimation of cognitive and motor abilities has a negative impact on short term goals attainment in the early rehabilitation of acute ischemic stroke patients.

Isolated anosognosia for cognitive deficit has no significant influence on rehabilitation goals achievement in nondemential acute stroke patients.

Negative influence of anosognosia for both motor and cognitive abilities on the results of rehabilitation interventions may be mediated by dysfunction of frontal lobes which is connected with parietal lobe and other cerebral structures.

The presence of anosognosia for motor and cognitive deficit requires the review of the short term rehabilitation interventions for acute stroke patients.

Chapter 85

VIDEO-BASED QUANTIFICATION OF PATIENT'S COMPLIANCE DURING POST-STROKE VIRTUAL REALITY REHABILITATION

Matjaž Divjak, PhD, Simon Zelič, BSc
and Aleš Holobar, PhD*

System Software Laboratory,
Faculty of Electrical Engineering and Computer Science,
University of Maribor, Slovenia

ABSTRACT

We present a video-based monitoring system for the quantification of a patient's attention to visual feedback during robot assisted gait rehabilitation. The patient's face and facial features are detected online and used to estimate the approximate gaze direction. This gaze information is then used to calculate various metrics of the patient's attention. Results demonstrate that such unobtrusive video-based gaze tracking is feasible and that it can be used to support the assessment of patient's compliance with the rehabilitation therapy.

Keywords: Video-based attention monitoring, gaze estimation, stroke rehabilitation, user compliance

INTRODUCTION

Stroke is the third most common cause of death in Western society, with about 4.7 million stroke survivors alive today. One of the hallmark residual impairments of stroke is post-stroke walking disability, which creates a stigma for patients, makes them more

* Correspondence: Matjaž Divjak, PhD, System Software Laboratory, Faculty of Electrical Engineering and Computer Science, University of Maribor, Smetanova ulica 17, SI-2000 Maribor, Slovenia. E-mail: matjaz.divjak@um.si.

susceptible to injury and directly affects their quality of life. Early rehabilitation therapy is crucial for significant improvements (1). In recent years, robotic systems have been widely tested and employed to retrain stroke patients. By imposing gait-like movements at a comfortable speed, such robotic devices are thought to provide many of the afferent cues regarded as critical to the retraining of locomotion (2).

However, a major problem with existing stroke therapies is patient non-compliance (3). Many stroke patients abandon the therapy because the process is too long, repetitive, and/or does not provide immediate results (4). The European project BETTER (5) recently addressed a new approach to gait rehabilitation by employing non-invasive brain-neural computer interaction (BNCI) based assistive technologies based on EEG (Electroencephalography), EMG (Electromyography) and IMU (Inertial Measurement Unit) sensors. In this article, we extend the BNCI-based modalities with a video-based attention monitoring system that allows automatic quantification and long-term monitoring of user attention. Such attention tracking does not require any sensors to be attached to the patient, making this method easy and fast to apply in stroke rehabilitation. Our main objective is to quantify the patient's attention to visual feedback, i.e., the amount of time the patient's gaze is actively following the displayed visual feedback and to inspect the possible impact of visual feedback on motor planning, as well as its short- and mid-term benefits.

Several studies have already examined the impact of visual feedback on stroke rehabilitation, but they mostly reported inconclusive results. They focused on quantification of results of rehabilitation, enhanced with different kinds of visual feedback, but their experimental designs did not allow for a reliable quantification of the attention a person is paying to stimuli. To the best of our knowledge, only psycho-physiological measures of a patient's attention to visual feedback has been reported in (6), while video-based assessment of attention has not been proposed in the field of rehabilitation.

Methods for real-time detection of the face, facial features, eye movements and gaze direction from video have attracted a lot of research in the past decade (7). Numerous algorithms for facial feature extraction have been proposed, mostly in the context of face detection and recognition (8). Currently, the most promising approaches rely on fusing multiple visual cues, such as combining local feature matching with intensity-based methods (9). Existing methods for the quantification of user attention to visual feedback have mostly been developed for Human-Computer Interaction applications and in order to help severely disabled people (10).

METHODS

An overview of our approach is depicted in Figure 1. The patient is fixed in a robotic gait trainer, which moves the patient's legs according to predefined rehabilitation scenarios, and is adapted to the patient's current walking abilities. In front of the patient is a large TV screen showing various types of visual feedback. A high speed video camera is mounted above the TV. The camera captures HD video of the patient's face, while simultaneously EEG data are recorded from 51 scalp sites and EMG data are recorded from both legs (tibialis anterior muscle).

Figure 1. Overview of the proposed approach for video-based estimation of patient's attention/compliance during robot-enhanced rehabilitation.

Figure 2. Five different types of visual feedback that are shown to the patient during therapy. Top row: the calibration screen for gaze direction estimation, and gait trainer's plots of current leg positions. Middle row: realistic VR environment from 1st and 3rd person perspective. Bottom row: special feedback displaying muscle activations.

The video streams are processed by our algorithms. First, frontal faces are detected and main facial features are extracted (corners of the eyes, pupil centers, mouth, tip of the nose). To suppress jitter from detection errors and body swings during walking, a Kalman filter is applied to the locations of the extracted facial features. Next, an active appearance model (AAM (11)) of the face with 59 facial landmarks is used to more accurately represent the current facial pose/expression. The relative distances between extracted landmarks are used to calculate the head pose and gaze direction. Finally, different metrics of the patient's attention/compliance are computed: the percentage of time the patient is observing the visual feedback, the spatial gaze distribution maps, the responses to actions in the virtual reality (VR) environment, etc.

We tested five different types of visual feedback (see Figure 2): a calibration screen for the initialization of our algorithms; 2D plots of current leg positions; 2D plots of muscle activations; and two realistic VR environments (walking in a park from 1st and 3rd person perspectives). The VR environments were created in OpenGL 3.3 and consist of ground, sky dome and male/female avatars. The avatars were created in Mixamo Pro Character Creator Tool and animated with Autodesk 3DS Max 2012. Both avatars have an underlying bone structure with all major joints modeled, allowing animation of almost all human movements. The actual avatar movement within the VR environment is controlled by kinematic data from the robotic trainer, so leg movements in VR world correspond with leg movements in real life.

The whole video processing system was designed for real-time operation, but the current version of the software is a mix of C++ and Matlab routines and runs at approximately 1 frame per second. Therefore, all video processing is currently performed offline, but (near) real-time operation is possible with further optimization of the code.

EXPERIMENTAL RESULTS

The proposed system was evaluated in an experiment that involved 4 stroke patients and consisted of 5 runs of robot assisted walking with different forms of visual feedback. In all runs, the patients were instructed to walk actively, maintaining a constant speed, and applying minimum force on the robot. A 42" screen was placed in front of the patient, 1.4 m away from his face. Each run lasted 4 minutes. For all types of visual feedback the walking speed remained constant. During the experiments videos of the patient's face were recorded to disk in HD resolution and later processed offline.

On average, the face was detected in 93% of video frames recorded (i.e., in practically all the frames with frontal faces whereas the profile faces were not detected). Eyes, mouth, nose, and pupils were accurately detected in more than 99% of detected faces (see Table 1). Detection of facial features was skipped in video frames where no face was detected. The average jitter of detected facial features was 1.0 ± 0.4 pixels. The AAM was successfully fitted to all frontal faces. The average jitter of AAM landmarks was estimated at 0.6 ± 0.4 pixels.

Table 1. Facial feature detection performance, estimated on three test videos

	Video 1 (gaze targets)		Video 2 (gaze targets)		Video 3 (VR 3 rd person)	
	frames	%	frames	%	frames	%
Whole video	9999	100 %	13391	100 %	10551	100 %
Face detection	9833	93.7 %	13193	98.5 %	10427	98.8 %
Detection of left eye	9805	99.7 % [*]	13174	99.9 % [*]	10419	99.9 % [*]
Detection of right eye	9769	99.3 % [*]	13179	99.9 % [*]	10408	99.8 % [*]
Detection of left pupil	9800	99.9 % [#]	13191	99.9 % [#]	10419	100 % [#]
Detection of right pupil	9769	100 % [#]	13187	100 % [#]	10408	100 % [#]
Detection of nose	9827	99.9 % [*]	13150	99.8 % [*]	10423	99.9 % [*]
Detection of mouth	9742	99.1 % [*]	13174	100 % [*]	10414	99.8 % [*]

^{*} Values normalized by the number of face detections.

[#] Values normalized by the number of eye detections.

Videos recorded during sessions with the screen displaying calibration targets were inspected by an expert and 9 approximate gaze directions (top-left, top-centre, top-right, bottom-left, bottom-centre, bottom right, left-centre, right-centre and centre of the screen) were manually annotated. The time periods corresponding to eye movements or eye blinks were ignored and were not annotated. Gaze direction was then calculated automatically by our algorithm and compared to the manually annotated gaze directions. The gaze directions were identified with average accuracy of $94\% \pm 6\%$. Most errors originated from distinguishing between top-left vs. bottom-left and top-right vs. bottom-right gaze directions.

Figure 3 shows an example of a patient's detected level of attention to visual feedback, estimated as percentage of time, in 1 second intervals, with gaze fixed to the TV screen; all gazes outside the screen were classified as non-attention.

Figure 3. An example of estimated level of a patient's attention to visual feedback during a 20 minutes long rehabilitation session (5×4 minutes).

Figure 4 presents an example of the estimated spatiotemporal gaze distribution metric. This metric shows relative frequency of identified gaze locations over a 4 minute long gait rehabilitation session. Brighter spots in the gaze distribution plots indicate areas with more frequent attention. Such maps support the identification of gaze targets (i.e., gaze hot-spots) and the assessment of spatiotemporal correlation between a patient's attention to visual feedback and other BNCI-based performance indices of gait rehabilitation.

Figure 4. An example of spatial gaze distribution plots (bottom row) for three different types of visual feedback (top row) shown to a patient during 4 minutes long gait rehabilitation sessions.

CONCLUSION

We developed and validated a video-based system for the robust tracking of a patient's face pose and gaze direction during robot-assisted lower limb rehabilitation therapy. The results (see Figures 3 and 4) show that such a system can be used to unobtrusively analyze patient's attention to displayed visual feedback and to provide a means for long-term quantification of visual feedback effects on the rehabilitation progress. It can also serve as an additional feature for other BNCI performance indices, such as similarity of motor modules, kinetic and kinematic profiles and brain patterns. For example, preliminary results show a significant correlation between attention to muscle activation plots and improvements in muscle activations during walking.

ACKNOWLEDGMENTS

This work was supported by the Commission of the European Union within Framework 7, grant agreement FP7-2009-7.2-247935 - "BETTER – Brain-Neural Computer Interaction for Evaluation and Testing of Physical Therapies in Stroke Rehabilitation of Gait Disorders". The authors would like to thank the personnel of Fondazione Santa Lucia in Rome, Italy, for organizing and performing the experimental recordings.

ABSTRACT

This chapter presents the colorimetric testing of rehabilitation games designed for the StrokeBack project. In this testing, the main subject of the investigation was how the people with different colour-blindness types can perceive the games. Many programmers and game designers do not pay attention to the accessible aspect of games. This accessibility implies that users who are colour-blind should be able to use the games the same way as the people with no vision impairment.

INTRODUCTION

The purpose of the research described here is to investigate the colour palette of virtual reality (VR) based rehabilitation games [1], as designed for the ‘StrokeBack’ [2] project. The goal of the StrokeBack project is to improve the speed and quality of stroke recovery through the development of a telemedicine system which supports ambulant rehabilitation in home settings for stroke patients with minimal human intervention. During our investigation we designed our VR based rehabilitation games in such a way that they would also be enjoyable for people who have colour-blindness.

The disorders in colour vision can be inherited and acquired. The cones’ red and green colour specific paint cell’s genes are linked to the X chromosome. Because of the gender-linked inheritance, this type of impairment is 20 times more prevalent in men. About 8% of

Caucasian males and 0.4–0.5% of females are “red-green” colour-blind. Inherited blue-blindness (tritanopia) is much rarer – only about 0.05% of the population can be detected. Some colour vision disorders are not inherited, they are so called “acquired”; several ophthalmological diseases can result in colour perception disorders (e.g., retinal diseases, glaucoma, cataracts, etc.) [3].

Stroke is a leading cause of death in the United States, killing nearly 130,000 Americans each year – that is 1 of every 20 deaths [4]. Every year, about 800,000 people in the United States have a stroke. About 610,000 of these are first or new strokes; 185,000 are recurrent strokes. Evidence from opticians indicates that about 10% of the male population are colour-blind. This, together with stroke incidence rate, leads to a statistically important problem.

STATE OF THE ART

The harmony of colours and proportions play an essential role in the appearance. Although many tend to neglect these issues, numerous scientific research studies are concerned with this field. All this is based on the colour perception of the eye, which, however unconsciously, may have an influence on patients’ decisions.

Scientists and artists over the last centuries [5–7] and nowadays [8] developed colour order systems where they defined rules to establish harmonic sets of colours. These colour harmony studies were based on the orderly arrangement of colours in the colour order system. The second group of authors [9, 10] defined colour harmony as an interrelationship of colours. The main principles of these studies are “complementary” and “analogous” but these concepts are not consistent among the studies. Also, the colour wheel was often adopted as a tool to define these basic relationships. Judd and Wyszecki [11] define colour harmony as a more universal concept: “when two or more colours seen in neighbouring areas produce a pleasing effect, they are said to produce colour harmony”. In addition, there is no consistency among the principles and the keywords of colour harmony: it is *completeness* according to Goethe [9], *order* according to Nemcsics [8] and Chevreul [10], and *balance* according to Munsell [6]. A quantitative model for two-colour combinations based on the CIECAM02 colour appearance model was developed by Szabó et al. [12]. Many other effects (i.e., age, cultural background) of colour harmony feeling have yet to be investigated.

In visual experiences, harmony is something that is pleasing to the eye. It engages the viewer and it creates an inner sense of order, a balance in the visual experience. When something is not harmonious, it is chaotic. At one extreme is a visual experience that is so bland that the viewer is not engaged. The human brain will reject under-stimulating information. The human brain rejects what it cannot organize, what it cannot understand. The visual task requires that we present a logical structure. Colour harmony delivers visual interest and a sense of order. Extreme unity leads to under-stimulation, extreme complexity leads to over-stimulation. Harmony is a dynamic equilibrium [13].

Colour deficiency is often neglected, as most people do not consider colour deficiency as a serious problem. Up to 15% of the population being affected by one form or another of colour deficiency [13]. It is quite common to see combinations of background and foreground colours that make web-pages, software, games etc. virtually unreadable for colour deficient users. Background, text, and graphics colours should be carefully chosen to allow

understanding for people with colour deficiency. Designing for colour deficient people is complicated. It is not simply a matter of green/red or yellow/blue combinations [13]. The most important issue in designing for colour deficient users is not to rely on colour alone to convey information and not to use colour as a primary means to impart information [14].

METHODS

Currently 3 games are built in the StrokeBack project:

- Break the Bricks game: practices horizontal (right-left) wrist movements – the player's task is to control the object at the bottom of the monitor;
- Birdie game: practices vertical (up-down) wrist movements – the player's task is to make a little bird fly and not let it fall;
- Gardener game: practices finger extension movements – the player's task is to pump a virtual sprinkler to make the plants grow by watering them.

These games can be used during the home rehabilitation process by the patients or replacing/enhancing clinical rehabilitation, thereby speeding up the process of recovery. These games are single player games which the patient can play by himself/herself. It is expected that the patients will play more with the games than they would do exercises. To these games several 'locations' were developed:

- Break the Bricks: default bricks, car, cake, duck, ship, train.
- Birdie: default meadow, cave (played with a bat), circus, forest, jungle, mountain, sea, town, winter.
- Gardener: bluebell, carrot, currant, geranium, grape, pepper, rose, strawberry, tomato, tulip.

Besides the 24 backgrounds for the 24 themes, more than 170 different objects had to be inserted, each of which had to be clearly visible. These were tested by different colour-blindness simulators and automatic testers.

Figure 1. Gardener's "Bluebell" and "Grapes" themes as seen by a person with good vision.

Figure 3. Testing of “BTB basic brick” theme with ETRE simulator (upper) and “Birdie jungle” theme with ASP.NET simulator (lower).

RESEARCH AND DEVELOPMENT

For the investigation four different colour-blindness simulators were used, which are accessible on the Internet and where pictures can be uploaded [15–17], and a downloadable software, ColorOracle [18], with which we could test the pictures appearing on the screen on the developer computer to find out how the users of different types of colour-blindness – deuteranopia, protanopsis, tritanopia – see the colours.

Testing and Contribution to the Field

Testing has been completed not only with the *ETRE*-, *ASP.NET* based-, and *Coblis*-simulators and the *ColorOracle* tester, but also with Variantor’s special glasses [19], with two individuals with good vision, and two persons with colour-blindness. Based on prevalence (10%) of colour-blindness in the male population, and the case that colour-blindness is aggravated by stroke [20], individual tests using a standard colour chart display has been conducted. Figure 5 shows the difference between normal colour vision (Figure 5a) and colour blindness in the red tone (Figure 5b).

Figure 4. Testing of “Gardener” with Cobli simulator (upper) and “Birdie cave” theme with ColorOracle tester.

The tests were completed by people with normal vision and those with colour-blindness. The visual elements of the games were not just tested with online applications. Out of the possible test subjects, we filtered for colour-blindness by applying the Farnsworth-Munsell 100 HueColor Vision test [21].

Figure 5. Original colour chart (left). Colour chart vision with Variantor glasses (right).

During the test, the subjects had to look at some parts of images taken from the games and were then asked questions regarding them. The questions concentrated on visibility and perceptibility, and the elements disturbing or obstructing visibility and perceptibility. Example questions are:

- *Jungle theme*: What kind of fruits could you see on the tree? How many? Which animal has a darker colour?
- *Cave theme*: How many bats have been in the cave? What objects could you see on the ground beneath the crab?
- *Forest theme*: Was there a wooden high-stand in the picture? What colour are the mushroom caps? How many separate clouds are visible?
- *Winter theme*: How many white animals could you see in the picture? From which direction did the bird (if there has been) fly to the image?
- *General questions*: What value did the achievement bar show on the right hand side?

Based on the test subjects' opinion, the achievement bar has been placed on the periphery of the screen and for the most of the time they have not even noticed that it is placed there. In the test subjects' judgement, the games' visibility and perceptibility is good, although they have indicated that, in the circus theme, the white and red stripes of the circus tent have been disturbing, which generated the vibrating effect. In the case where the recurrence of some image elements have been questioned, the elements have been recognized in the pictures and the subjects have even been able to determine the correct number, but the colours of the elements could not be recalled. As an example, in the garden topic the subjects were able to tell how many tulips have there been on the picture, but they could not tell the colours of the flowers. Responses to questions on colour balance include remarks that the plants in the picture mostly fade into the greenish hue background and, in case of the jungle theme, the green parrot can hardly be noticed between the leaves of the tree.

For some of the users and test subjects the noisiness and pixel problems due to the low image resolution were disturbing. The test subjects have also emphasized some situations that had disconcerting effects, for example when combinations of colours have been shown which physically interrupted the focusing of the eyes, as in the case of combination red-blue colours.

The results of the tests have shown that the observers – despite their colour vision deficiency – have seen picture elements taken from the game appropriately, the small details

having been recognized and identified. The separation, observation and recalling of the games' image elements did not cause any problems for the validly colour-blind test subjects.

CONCLUSION AND PLANNED ACTIVITIES

We have not found any publications that consider the testing of colours of rehabilitation games, lending credence to our view that developers do not think about the colour-blind people. As a result of our testing, we reached the conclusion that, within the StrokeBack games, the objects are clearly visible, so the colour-blind patients can practice in the same way as the normal sighted. In future, games should not only be tested with the software, but also with other simulation goggles (tunnel-vision, macula or lens degeneration). Clinical tests of efficiency (which refer to the colour testing and efficiency of the rehabilitation) were started in June, 2014, and future reporting will detail these results.

STROKE-PRONE SPONTANEOUSLY HYPERTENSIVE RATS: INSIGHTS ON NEURONAL VULNERABILITY AND ASTROCYTIC ABNORMALITIES IN STROKE

Kazuo Yamagata*

Department of Food Bioscience and Biotechnology, College of Bioresource Sciences, Nihon University (NUBS), Kameino, Fujisawa, Kanagawa, Japan

ABSTRACT

Stroke evokes cerebral infarction and hemorrhaging and is associated with very high mortality. Stroke-prone spontaneously hypertensive rats (SHRSP) exhibit severe hypertension, and more than 95% of them die of ischemic cerebral stroke. In SHRSP rats, ischemic stresses such as hypoxia and re-oxygenation result in enhanced neuronal cell death *in vivo* and *in vitro*. Specific characteristics of brain cells from SHRSP rats contribute to their susceptibility to stroke. For example, the susceptibility of SHRSP rat neurons to cell death is partly due to an insufficiency of mitochondrial redox regulation and a deficiency of the apoptosis-inhibitory protein Bcl-2. However, the proliferative capacity of astrocytes isolated from SHRSP rats is significantly increased compared with those from the parental Wistar Kyoto Wistar Kyoto strain. In astrocytes, lactate production acts as an energy source for neuronal cells, and is reduced in SHRSP cells compared to normal WKY rats. Furthermore, SHRSP astrocytes show decreased production of neurotrophic factors such as glial cell line-derived neurotrophic factor (GDNF) and L-serine when compared to WKY astrocytes after hypoxia and re-oxygenation. After stroke, neuronal survival alone may be insufficient to promote recovery. Thus, in recent years, there has been an elevated focus on the roles of astrocytes in stroke. In this review, we provide insights on neuronal vulnerability and astrocytic abnormalities during stroke.

1. INTRODUCTION

Stroke induces cerebral infarction and hemorrhaging and is associated with very high mortality worldwide [1]. At the onset of stroke, brain dysfunction and neuronal loss occur due to an insufficient blood supply to the brain. Stroke-prone spontaneously hypertensive (SHRSP) rats develop severe hypertension, greater than 200 mm Hg, and more than 95% of them die of stroke [2, 3]. In SHRSP rats, enhanced sodium intake accelerates the rise in blood pressure (BP) and cerebral ischemia induces the appearance of cerebral vasogenic edema [4]. Therefore, SHRSP rats are widely used as an experimental model of human stroke [3].

Numerous studies using SHRSP rats have provided valuable information regarding human stroke and have identified genetic susceptibility to particular types of cerebrovascular diseases associated with stroke [5]. For example, twenty minutes of cerebral hypoxia stimulation in SHRSP rats potentiated a large efflux of glutamate, causing significant but delayed neuronal death in region CA1 of the hippocampus, whereas rats from the parental Wister Kyoto (WKY) rat strain did not exhibit this pathology under the same conditions [6]. Thus, it appears that hippocampal neurons of SHRSP rats are innately vulnerable to ischemic stimulation such as hypoxia. However, Ca²⁺ channel blockers were able to prevent neuronal

cell death in SHRSP rats [7]. It was reported that neuronal production of hydroxyl radicals was significantly elevated after reperfusion or hypoxia in SHRSP rats [6]. In contrast, neuronal expression of thioredoxin (Txn) and Bcl2 significantly decreased in SHRSP rats compared with WKY rats. Both *in vitro* and *in vivo* studies have demonstrated that SHRSP rat neurons are more vulnerable than WKY neurons during cerebral ischemia-hypoxia [8, 9]. In these reports, it was suggested that unknown factors other than a genetic weakness in the neurons themselves also played a role in accelerating cell death in SHRSP rats during cerebral ischemia [8, 9]. For example, the astrocytes of SHRSP rats were largely altered by ischemic stimuli such as hypoxia. Lactate production from these astrocytes (which acts as an energy source for neuronal cells) was decreased in SHRSP rat cells compared to WKY astrocytes [10]. In addition to decreased lactate production, during hypoxia and reoxygenation (H/R) SHRSP astrocytes also showed reductions in glial cell line-derived neurotrophic factor (GDNF) and L-serine in comparison to WKY astrocytes. Furthermore, the production of L-serine and the expression of lactate transporter occurred at lower levels in SHRSP astrocytes than in WKY astrocytes after exposure to arginine vasopressin (AVP) [11].

Oxygen reperfusion after cerebral ischemia rapidly produces a large quantity of reactive oxygen species (ROS) and induces neuronal cell death in SHRSP rats. However, the pathogenic mechanisms of stroke in SHRSP rats are not well understood. Cerebral ischemia induces destruction of the blood-brain barrier (BBB), subsequently increasing edema and nervous system cell death. In SHRSP rats, vascular endothelial injury is observed at multiple sites following BBB leakage, ultimately resulting in vessel rupture [12, 13]. After stroke, neuronal survival alone may be insufficient to promote full recovery. Thus, in recent years there has been an elevated focus on the roles of astrocytes in stroke. In this review we present an overview of the cellular characteristics and function of SHRSP and WKY rat neurons and astrocytes during cerebral ischemia and hypoxia.

2. NEURONAL VULNERABILITY AND REDOX REGULATION IN THE BRAIN OF SHRSP RATS UNDER ISCHEMIC CONDITIONS

2.1. Vulnerability of Neuronal Cells in SHRSP Rats

In the SHRSP rat stroke model, ischemic stimulation is considered to be the most effective mechanism for promoting neuronal cell death during cerebral ischemia. *In vivo* studies have shown that a cerebral ischemic event lasting 20 minutes can induce the production of large amounts of glutamate, causing delayed neuronal cell death in the CA1 region of the hippocampus of SHRSP rats [6]. Other studies have also investigated these effects in cultured neuronal cells isolated from fetal brains of SHRSP and WKY rats. The neuronal cells were cultured for 6 to 24 hours under 1% O₂ hypoxic conditions then subsequently exposed for 1.5 to 5 hours to a reoxygenated state to assess cell viability [8]. None of the neuronal cells were stained by trypan blue, indicating the absence of cell death in both strains. Under these conditions, 65%-85% of WKY neuronal cells survived even after 36 hours of hypoxic culture. In contrast, neuronal cells from SHRSP rats showed a marked increase in the percentage of cell death, with almost all of the dead cells being apoptotic [8]. After exposure to hypoxic conditions, with only 1.5 hours of reoxygenation, only 10 to 30%

of neuronal cells survived. The total rate of neuronal cell death in WKY rats and SHRSP rats was 41% and 78%, respectively. The rate of necrosis in neuronal cells of WKY rats and SHRSP rats was 12% and 15%, whereas the rate of apoptosis was 29% and 63%, respectively. Three hours of reoxygenation after hypoxia induced cell death in 68% of WKY neuronal cells, whereas 99% of SHRSP neuronal cells had died. However, little or no DNA fragmentation was observed in neuronal cells of SHRSP rats after culture under normoxic conditions (20% oxygen). After 36 hours of hypoxia and 3 hours of reoxygenation, a marked enhancement in DNA fragmentation was observed, and was generally localized to areas containing many lipid droplets [8]. The apoptotic stages of neuronal cell death were also classified [8, 9]. (A) During the early stage of apoptosis, neuronal axons were present but dendrites were lost and many lipid droplets could be observed in the neuronal cell bodies. (B) During the next stage of apoptosis, cell shrinkage was observed. (C) This was followed by continued development of apoptotic cells. (D) During the final stage of apoptosis, both the neuronal cell membranes and nuclei disappeared.

2.2. ROS Production and Neuronal Injury

Cerebral ischemia induces the rapid generation of a large amount of reactive oxygen species (ROS) and induces neuronal cell damage. This is particularly evident in SHRSP rats in which oxidative stress induces neuronal cell death and redox changes. For example, SHRSP rats generate a large amount of ROS that leads directly to neuronal death after ischemic stimulation such as the reoxygenation that occurs after hypoxia [14]. Cerebral ischemia increases the intracellular level of calcium ions and activates calcium-dependent proteases. Moreover, these changes activate xanthine dehydrogenase (XDH) and xanthine oxidase (XOD). In SHRSP rats, the XOD inhibitors allopurinol or superoxide dismutase prevented apoptosis of neuronal cells during hypoxia and oxygen reperfusion [8]. Similar changes occur upon reperfusion of the ischemic rat heart in which activation of XOD induces ischemic reperfusion injury in cardiomyocytes [15]. Here, XOD is a significant source of free radicals and induces oxidative injury. In cerebellar granule cells, glutamate triggers a large influx of Ca^{2+} which induces the rapid conversion of XDH into XOD and production of ROS [16]. Thus free radicals are produced by reoxygenation after cerebral ischemia and enhance injury of neuronal brain cells [17]. Free radical production is one of the initial steps in a series of events leading to neuronal degeneration and death. The free radical-generating enzyme XOD may be a central regulator of postischemic neuronal cell injury. Alternatively, it has been reported in rats that stimulation by middle cerebral artery occlusion (MCAO) can induce brain damage, massive neuronal loss, and DNA fragmentation. These MCAO experiments demonstrated that endoplasmic reticulum stress enhances brain damage after cerebral ischemia and reperfusion in rats [18].

2.3. Redox Regulation in SHRSP Rats

Activation of antioxidants and enzymatic antioxidant pathways reduces ROS formation such as the hydroxyl radicals produced during H/R and is beneficial for preventing neuronal injury [19] (Pan et al., 2015). This neuronal protection might be achieved by increasing the

levels of antioxidant substances such as vitamin E [20]. Namely, for the prevention of neurotoxicity by cerebral ischemia, redox regulation through increased levels of antioxidants and antioxidant enzymes is important. Moreover, decreased glutathione (GSH) levels in neuronal cells of SHRSP rats have been associated with neuronal vulnerability [21]. To further investigate this, the redox status of tissues from WKY, SHR and SHRSP rats were investigated. The SHR rat strain showed enhanced oxidative stress and impaired thioredoxin (Trx) expression. Induction of Trx was impaired after treatment with angiotension II in blood mononuclear cells isolated from SHR or SHRSP rats compared with those isolated from WKY rats [22]. The expression of Trx mRNA was detected prior to hypoxia, however, following hypoxia and after reoxygenation Trx expression was significantly reduced in neurons of SHRSP rats compared to WKY rats [23]. Recent studies have demonstrated that Trx has a protective effect on neurons and is closely related to oxidative stress and apoptosis in cerebral ischemic injury [24]. Experiments were conducted to validate the neuroprotective effect of recombinant human Trx-1 and its potential mechanisms against ischemic damage after MCAO in mice. Trx-1 significantly improved neurological function and decreased cerebral infarction and apoptotic cell death 24 hours after MCAO. In addition, Trx-1 resulted in a significant decrease in heme oxygenase-1 (HO-1) which is protective against oxidative stress. These results indicated that Trx-1 exerts a neuroprotective effect on cerebral ischemic injury. Trx-1 may represent a therapeutic approach for reducing oxidative stress-induced neuronal apoptotic cell death in acute ischemic stroke. Trx proteins act against ROS via the sulfhydryl (-SH) group. In addition to ROS antagonism, Trx proteins have many functions pertaining to intracellular signal transduction. Thus, reduced expression of Trx is associated with an attenuation of the defense system of antioxidants during oxidative stress in SHRSP rats. This subsequently results in reperfusion-induced neuronal cell death. These findings suggested that redox regulatory functions in SHRSP rat neurons were markedly inhibited by oxidative stress stimulation after hypoxia, and such changes may be involved in neuronal vulnerability [25].

2.4. Preventive Effects of Vitamin E

Vitamin E is a powerful antioxidant and its effects on reduced oxidative stress in ischemic stroke have been demonstrated [26]. Specifically, vitamin E, which is present in biological membranes, contains a hydroxyl group that reacts with unpaired electrons and can be reduced to form peroxy radicals. The relationship between vitamin E and reactive oxygen species has been demonstrated in mouse models of vitamin E deficiency. These results showed decreased superoxide production during alpha-tocopherol deficiency [27]. The major antioxidant effect of vitamin E is to quickly add alkoxy radicals and hydrogen to peroxy radicals. Thus, the mechanism of vitamin E is to act as a chain-breaking antioxidant that blocks reactive oxygen metabolic cascades [28, 29]. Vitamin E induces SOD, GST and catalase, and also enhances the levels of GSH and reduces lipid peroxidation. The effects of vitamin E were shown to be more effective than those of vitamins A or C [30]. In WKY and SHRSP rat strains, vitamin E prevented neuronal cell death associated with cerebral ischemia-reperfusion, particularly apoptosis [8, 20]. The overproduction of oxygen-free radicals that occurs in the tissues of SHRSP rats is associated with reoxygenation injury after hypoxia. The effects of vitamin E were also investigated during hypoxia and oxygen reperfusion using

cortical neurons isolated from WKY and SHRSP fetal rat brains at 15 days of gestation. Hypoxia increased the rate of neuronal cell death in SHRSP rats, but did not increase cell death in WKY rats [8, 21] (Figure 1). The percentage of neuronal cell death that occurred mainly via apoptosis during hypoxia and reoxygenation was remarkably higher in neurons from SHRSP rats than from WKY rats. However, in SHRSP rats, neurons incubated with 50 to 300 $\mu\text{g/mL}$ of vitamin E remained intact [8, 21] (Figure 2). Using HPLC, the accumulation of vitamin E was confirmed within the mitochondria of neuronal cells after 36 hours of hypoxia. Vitamin E (when dosed at 50 $\mu\text{g/mL}$) accumulated most effectively into the mitochondria of neuronal cells in SHRSP rats. The presence of vitamin E is most enriched in the microsomal cell membranes of mitochondria of the liver and heart. Transport of vitamin E to the mitochondria or microsomes is achieved by vitamin E binding to the alpha-tocopherol transfer protein (TTP) [31, 32]. Genetic variation in the TTP gene can induce ataxia with vitamin E deficiency. Thus, vitamin E might have significant inhibitory effects against neuronal cell injury after incorporation into biological membranes, as observed in the mitochondrial membranes of SHRSP rats.

In neurons in culture matured, they were incubated in 1% O_2 for 36 hours without (A) or with (B) vitamin E (100 μM). After the hypoxic culture, they were maintained in 21% O_2 for 1.5 hours with or without vitamin E (100 μM). Vitamin E treatment was carried out as described in a previous report (Tagami et al., 1998). Cont (normoxia); 21% for 36 hours, Hypoxia; 1% O_2 for 36 hours. H/R; 1% O_2 for 36 hours plus 21% O_2 for 1.5 hours. Asterisk (*); $p < 0.001$ compared with WKY rats. Values are the mean $\pm$ SE ($n = 7$). Citation from Tagami et al., (1998) and Yamagata et al., (2009).

Figure 1. Inhibition of cell death in cortical neuronal cells by vitamin E during hypoxia and reoxygenation in WKY and SHRSP rats.

In neuronal cells in culture, they were incubated in 1% O₂ for 36 hours with (A) or without (B) vitamin E (100 μM). Vitamin E treatment was carried out as described in a previous report (Tagami et al., 1998). Citation from Tagami et al., (1998) and Yamagata et al., (2009).

Figure 2. Preventive effects on ischemic neural cell death of vitamin E on neurons of SHRSP rats.

2.5. Apoptosis and Neuronal Cell Death in SHRSP Rats

The mechanism of neuronal cell death in SHRSP rats is likely apoptosis [8, 21]. The expression of apoptosis-inducing molecules such as Bax was increased in injured neuronal cells. Conversely, the expression of apoptosis-inhibiting molecules, such as Bcl-2 and Bcl-XL, increased in the surviving neurons of rat brains following global ischemia [33]. Distinct expression of some members of the bcl-2 gene family may play an important role in determining the sensitivity of neurons to ischemic cell death [34]. Expression of bcl-2 after hypoxia and reoxygenation was examined by real-time quantitative-PCR using cultured neuronal cells isolated from SHRSP and WKY rats [23, 35]. In SHRSP rat neurons, apoptosis-inducing molecules such as Bax were increased after damage. The pattern of bcl-2 gene expression in SHRSP and WKY rats showed the most marked difference after 30 minutes of reoxygenation in which bcl-2 was significantly reduced in SHRSP compared to WKY rats [20] (Figure 3). Thus, the sensitivity of neuronal cells to ischemic stress likely accelerates neuronal cell death during stroke in SHRSP rats.

3. CHARACTERISTICS OF SHRSP RAT ASTROCYTES AND CORRELATIONS WITH STROKE

3.1. Roles of Astrocytes in Stroke

Neuronal survival alone may be insufficient to promote recovery after stroke. Thus, in recent years there has been an elevated focus on the roles of astrocytes in stroke. Astrocytes

play a number of essential roles in a properly functioning central nervous system (CNS). In particular, astrocytes are important for regulating changes in vascular tone in response to neuronal activity. For example, astrocytes promote the formation and integrity of the BBB, as well as promote synaptogenesis and respond to the production of inflammatory molecules [36]. In stroke, the multiple functions of astrocytic activity are affected. After ischemic injury, reactive gliosis has been observed in the brain of humans and in animal models of stroke [37]. Previous studies have suggested that the phenotypic conversion of astrocytes from the resting to reactive state may be associated with many brain diseases [38]. Severe brain injury results in the proliferation and migration of reactive astrocytes; specific key molecules play a role in regulating the pathophysiological functions of reactive astrocytes [39].

In SHRSP rats, enhanced BP destroys pericytes and promotes the permeability of endothelial cells, causing astrocytic swelling around the blood vessels [40]. Surprisingly, swelling of the astrocytes occurs before neuronal cell death in SHRSP rats [40]. Thus, the astrocytic swelling observed in SHRSP rats may promote neuronal death during ischemic stroke [41]. In cultured astrocytes isolated from SHRSP rat brains, the cell growth rate in 10% FBS was faster than in astrocytes from WKY rats. Specifically, the doubling time of cultured astrocytes isolated from SHRSP rats was 21 hours, whereas that of WKY rat astrocytes was 30 hours. These data demonstrate the elevated growth capacity of astrocytes from SHRSP rats, and suggest that the large number of reactive astrocytes in SHRSP rats may be detrimental. Furthermore, SHRSP rats showed enhanced astrocytic reactivity in response to epidermal growth factor (EGF) compared to astrocytes from WKY rats, and this was associated with increased cell number. These proliferative astrocytes were observed around infarcted tissue in ischemic brains and were immunoreactive for the EGF receptor (EGFR) [42]. Another report demonstrated that transforming growth factor- α (TGF- α) is a ligand for the EGF receptor (EGFR), and can prevent ischemic neuronal damage. The enhanced proliferative activity of SHRSP rat astrocytes suggests that neuronal damage in cerebral ischemia may be due to an excessive response to EGF [43]. Furthermore, it has been reported that ischemic insult enhanced the expression of platelet-derived growth factor (PDGF) β -receptor mRNA and protein levels in the brain of SHR rats [44]. Thus, the enhanced proliferative activity of astrocytes from SHRSP strain rats suggests that cerebral vascular lesions in cerebral ischemia may be due to dysfunctional responses to EGF and PDGF [42, 44].

3.2. GDNF Production in Astrocytes and in SHRSP Rats

Astrocytes regulate the uptake of glutamate [45], water and ion homeostasis [46], the induction of the blood-brain barrier (BBB) [47], as well as induce production of cytokines [48] and neurotrophic factors [49]. For example, after brain injury, neuronal cell regeneration is regulated through the release of neurotrophic factors from astrocytes [49, 50]. In addition, GDNF is released after ischemia and has a protective effect against ischemic brain injury [51]. The release of GDNF was shown to be enhanced after transient MCAO in the cerebral cortex [52] or after kainic acid injection [53]. Moreover, the expression of GDNF and its receptor are induced in brain tissue under post-ischemic reoxygenation conditions [54]. Previous studies have demonstrated that the vulnerability of SHRSP neurons to cell death under ischemic conditions such as hypoxia and reoxygenation was associated with decreased

GDNF production by SHRSP astrocytes [55]. Cultured astrocytes isolated from SHRSP rats released higher levels of GDNF than did WKY rats [23] (Figure 4). This suggests that during injury of the CNS in SHRSP rats, the attenuated release of GDNF by astrocytes may be associated with neuronal vulnerability. Furthermore, after 1% O₂ hypoxia and 1.5 or 6 hours of reoxygenation, the release of GDNF was significantly lower in astrocytes from SHRSP strain rats than WKY rats. Similarly, the addition of sphingosine 1-phosphate (S1P) [56] and adenosine [57] partially blocked the release of GDNF from cultured astrocytes isolated from SHRSP rats. S1P is a lysophospholipid secreted by activated platelets [58], and induces apoptosis in neuronal cells of the CNS [59]. Under normal conditions, increased S1P attenuates GDNF release by astrocytes and reduces neuronal injury via the production of neurotrophic factors. However, the level of GDNF released by adenosine-exposed astrocytes was significantly reduced in SHRSP rats compared with WKY rats. In the CNS, adenosine has immediate effects, such as in neurotransmission, and longer term neurotrophic effects that promote changes in cell metabolism and structure, in addition to neuroprotective functions [60, 61]. Adenosine increases the level of several growth factors in ischemic brain tissues, likely as part of a preventive response. Furthermore, within the extracellular space, adenosine acts as an intercellular signaling molecule, however, at high levels it induces apoptosis in the CNS [62]. These results indicate that the release of GDNF is regulated by S1P and adenosine during reoxygenation and ischemia. Although the pathogenesis of GDNF release by SHRSP rats is unknown, the metabolic properties of SHRSP rats may be related to the increased expression of GDNF.

Total cellular RNA was isolated from cultured cortical neurons at the following four time points; untreated (Pre), 24 hours of hypoxia (1% O₂), 24 hours of hypoxia, and 30 and 90 minute of reoxygenation (20% O₂). Total RNA was transcribed with reverse transcriptase and amplified by real-time quantitative PCR. These results represent three independent experiments. Bars are the mean $\pm$ SD (n = 4). *P, 0:01 compared with WKY (control) neurons (oblique line column); n.s., not significant. Modified from Yamagata et al., (2000).

Figure 3. Expression of Bcl-2 and TRX-1 mRNA during hypoxia and reoxygenation of cultured neuronal cells isolated from WKY and SHRSP rats.

Confluent astrocytes were exposed to normoxia (5% CO₂ and 95% air) for 2 hours in a sealed chamber and then to hypoxia (1% O₂, 5% CO₂, and 94% N₂) for 2, 5, and 24 hours. Total cellular RNA was isolated from cultured astrocytes. Total RNA was transcribed with reverse transcriptase and amplified by real-time quantitative polymerase chain reaction (PCR). Bars are the mean $\pm$ SD (n = 5). *P < 0.05 compared with WKY (control) astrocytes. Citation from Yamagata et al., (2002).

Figure 4. Regulation of glial cell line derived neurotrophic factor (GDNF) mRNA expression during hypoxia and reoxygenation in astrocytes isolated from SHRSP rats.

3.3. Regulation of L-Serine Production and Neuronal Cell Survival

L-serine plays an important role in neuronal survival by evoking a variety of biological responses within astrocytes. In the brain, L-serine is synthesized by 3-phosphoglycerate dehydrogenase (3-PGDH) in astrocytes but not in neuronal cells [63]. L-serine produced by astrocytes is transported to the extracellular space by neural amino acid transporter ASCT1 and becomes available to neuronal cells where it promotes neurite outgrowth from ganglion neurons and enhances neuronal cell survival [64, 65]. The production of L-serine is induced in response to glutamate, kainic acid (KA) and free radicals in excitotoxic lesions which promote degenerative diseases in the CNS [66]. Furthermore, excitotoxic damage induces the expression of 3-PGDH and ASCT1 proteins in the hippocampus of the mouse brain [66]. A previous report has characterized the altered regulation of L-serine in astrocytes of SHRSP rats. In cultured astrocytes isolated from SHRSP rats, the glutamate-enhanced stimulation of L-serine production was reduced [35, 23] (Figure 5). Moreover, the level of L-serine and expression of PHGDH and ASCT1 was decreased in astrocytes of SHRSP rats compared with WKY rats after glutamate exposure. Thus, reduction in L-serine release from astrocytes may be associated with the neuronal vulnerability to injury in SHRSP rats during stroke. During cerebral ischemia, astrocytic swelling induces ischemic neuronal cell death. Arginine vasopressin (AVP) and hypoxia can both contribute to ischemia-induced astrocytic swelling such as edema [67]. Additionally, AVP also induces inflammatory molecules in traumatic neuronal injury [68]. Ischemic conditions such as hypoxia and stimulation of AVP can affect cerebral cell volume [69, 70], ion uptake by cerebral cells via Na/H exchange (NHE) [71] and

activity of the Na-K-Cl cotransporter (NKCC) [72, 73]. Combined, these results suggest that AVP might contribute to astrocytic swelling induced by hypoxia and reperfusion in SHRSP rats. L-serine released by astrocytes has been shown to support neuronal cell survival. For example, L-serine synthesis and the expression of ASCT1 were shown to be essential for neuronal survival and differentiation [74]. As described above, the expression of 3-PGDH and ASCT1 proteins is induced by excitotoxic lesions in the mouse hippocampus [66]. Moreover, AVP enhanced the production of L-serine and the expression of neural amino acid transporter ASCT1 in WKY/Izm and SHRSP/Izm astrocytes [11]. The production of L-serine and the expression of ASCT1 showed greater attenuation in SHRSP/Izm than in WKY/Izm astrocytes [11] (Figure 6). The AVP-induced decrease in ASCT1 expression in astrocytes is associated with lowered L-serine production in SHRSP/Izm astrocytes. Therefore, L-serine production might be regulated by astrocytes in response to a variety of molecules such as AVP that enhance brain edema in SHRSP rats.

3.4. Regulation of Inflammation by HMGB1 in SHRSP Astrocytes

The High-mobility group box 1 (HMGB1) protein has been reported to be involved in inflammatory responses associated with stroke after ischemia [75]. HMGB1 controls nucleosomal structure stabilization, and regulates inflammation during recovery after stroke [76, 77, 78]. Hypoxia has been shown to enhance HMGB1 expression in neurons and astrocytes [79]. Moreover, after hypoxia, HMGB1 induces the breakdown of the BBB during ischemic insult [80]. HMGB1 was shown to be produced by neurons and astrocytes and exacerbates ischemic neurodegeneration [79]. Production of HMGB1 also promotes endothelial progenitor cell-mediated neurovascular remodeling during stroke recovery in reactive astrocytes [81]. Moreover, during oxygen glucose deprivation and reperfusion, astrocytic HMGB1 release enhances endogenous neural stem cell and/or progenitor cell proliferation [82]. These results suggest that HMGB1 may play an important role in brain tissue repair after an ischemic event [82]. An early study examined the expression of AVP-induced HMGB1 in cultured primary astrocytes isolated from WKY, SHR, SHRSP and SHRpch1_18 rats. AVP induced HMGB1 expression at 50 and 100 nM and was significantly higher in SHR, SHRSP, and SHRpch1_18 rat astrocytes than in WKY astrocytes. The data suggest that HMGB1 may be associated with the early stages of the inflammatory response [80]. This property of SHRSP, SHR and SHRpch1_18 rats is likely an important contributor to enhanced astrocytic inflammation and could explain how AVP augments the inflammatory reaction and promotes neuronal cell death.

3.5. Stimulation of TNF- α and Expression of Vascular Cell Adhesion Molecule-1 in Astrocytes

Following exposure to tumor necrosis factor- α (TNF- α), the expression of vascular cell adhesion molecule-1 (VCAM-1) in SHRSP rat astrocytes was enhanced compared to that in WKY rats. The expression of TNF- α and adhesion molecules is related to early neurological exacerbation and infarct volume during stroke [83, 84]. TNF- α is produced by microglial cells and infiltrating macrophages following ischemic stroke [85]. In astrocytes of

SHRSP rats, the expression of monocyte chemotactic protein-1 (MCP-1) was enhanced compared with to normoxic conditions in H/R. The suppression or genetic lack of these adhesion molecules has been reported to decrease infarct volume and edema, and/or mortality in different animal models of ischemic stroke [86]. Enhanced levels of adhesion molecules or TNF- α may be induced by stroke in SHRSP rats during H/R. Thus, the alteration of astrocytic function promotes neuronal cell death during stroke in SHRSP rats.

The confluent growth of astrocytes was arrested for 1 day in FBS-free DMEM containing 0.2% FBS. (a) Glutamate (100 μ M) was added or the cultured astrocytes WKY and SHRSP. Citation from Yamagata et al., (2006).

Figure 5. Effect of glutamate on the secretion of l-Ser in cultured astrocytes isolated from WKY and SHRSP rats.

Confluent WKY or SHRSP astrocytes were exposed to zero, 10, 50 or 100 nM AVP for 8 hours, after which total cellular RNA was isolated for analysis by RT-PCR. Brackets show comparisons of WKY/Izm vs. SHRSP/Izm astrocytes at the same AVP dose. Columns show means $\pm$ SE (n = 4). AVP, arginine vasopressin; W, WKY; P, SHRSP, rRNA, 18S ribosomal RNA. *P < 0.05 compared with WKY (control) astrocytes. Citation from Yamagata et al., (2014).

Figure 6. Arginie vasopressin induced ASCT1 gene expression in WKY and SHRSP astrocytes.

CONCLUSION

The degree of neuronal cell death in the SHRSP rat strain is markedly higher than that in the WKY strain [8, 9]. The properties of SHRSP neuronal cells, unlike those of WKY rats, might be an important factor in the elevated frequency of stroke in cerebral ischemia. In SHRSP rats, vitamin E reduces neuronal cell damage caused by ROS generated after cerebral ischemia. Thus, antioxidants such as vitamin E could be used as a treatment for oxidative stress-mediated neuronal diseases. Vitamin E and other antioxidants may regulate redox potential and apoptosis-related proteins. Furthermore, in SHRSP rats, astrocytic properties contribute to the development of brain disorders. In SHRSP rats, neuronal vulnerability and reduction of astrocytic neurotrophic factors, such as GDNF and L-serine, were demonstrated under cerebral ischemic stroke conditions.

Furthermore, after ischemic stimulation, the production of MCP-1 is strongly enhanced in astrocytes of SHRSP rats [87]. The expression of VCAM-1, MCP-1 and HMGB1 is also markedly elevated in astrocytes of SHRSP rats compared with WKY rats [17]. Of particular note, HMGB1 is known to induce inflammation in brain cells. In summary, neuronal cell vulnerability and abnormal regulation of the supportive functions of astrocytes may elevate the risk of stroke in SHRSP rats.

PURE MOTOR MONOPARESIS DUE TO ISCHEMIC STROKE

Akiyuki Hiraga*, MD

Department of Neurology, Chiba Rosai Hospital,
Chiba, Japan

ABSTRACT

Pure motor monoparesis (PMM), an isolated paresis due to ischemic stroke in a single arm or leg without higher, cranial, or sensory dysfunction, is an uncommon clinical condition. Cortical infarctions of the precentral knob and anterior cerebral artery territory are the most commonly reported PMM lesions affecting the upper and lower extremities, respectively. Other reported lesion sites include the subcortex, corona radiata, internal capsule, and brainstem; however, they are reported less frequently than cortical infarctions because the descending motor axons in these areas are highly compacted. Large artery atherosclerosis and cardiogenic embolism are considered as the two main etiologies of cortical infarction. In earlier studies, PMM cases due to lacunar infarctions were presumed to be rare. However, lacunar infarction PMM cases have been increasingly reported in the recent years. The weakness patterns in PMM are complex and include proportional and distal- or proximal-dominant weakness. Distal-dominant weakness is the most common PMM type. Some patients exhibit isolated finger paresis or predominant weakness of specific fingers. Although the overall prognosis is favorable in PMM due to ischemic stroke, short- and long-term prognosis depends on risk factors and stroke mechanisms. The diagnosis is sometimes difficult because many cases of PMM lack pyramidal signs and mimic peripheral nerve damage. Therefore, acute monoparesis, particularly in elderly patients with conventional risk factors, should be carefully assessed. Diffusion-weighted imaging is the most useful diagnostic tool for PMM due to ischemic stroke as small cortical infarctions often cannot be detected by conventional sequences of magnetic resonance imaging, or computed tomography. This review provides an update on clinical features, lesion topography, and prognosis of PMM due to ischemic stroke.

Keywords: pure motor monoparesis, cerebral infarction, diffusion weighted magnetic resonance imaging

INTRODUCTION

Pure motor monoparesis (PMM) of a single arm or leg due to ischemic stroke (IS) without higher, cranial, or sensory symptoms/disturbances is a rare condition [1, 2]; however, it is a clinically important stroke syndrome that can easily be misdiagnosed and/or confused with nonvascular causes of weakness [3, 4]. Undoubtedly, correct diagnosis of acute stroke is of paramount importance to clinicians to enable selection of appropriate treatments and to ensure prevention of acute complications, including recurrent stroke [5]. Given the rarity of PMM due to IS, which often mimics peripheral neuropathy and is sometimes difficult to detect by computed tomography (CT) or conventional magnetic resonance imaging (MRI), many patients with PMM due to IS might have been overlooked until recently. The diagnosis of PMM due to IS has always been a clinical challenge not only for general practitioners but also for neurologists. This review provides an update on the frequency, lesion topography, clinical features, mechanisms, and prognosis of PMM due to IS. Moreover, this review aims to aid clinicians in improving the accurate diagnosis of PMM due to IS, with a focus on differential diagnosis from nonvascular causes of PMM, especially from peripheral nerve damage.

A BRIEF HISTORY OF PMM DUE TO IS

Lhermitte described “pseudoperipheral palsy” in 1909 in patients with a sensorimotor deficit in fingers due to central nervous system lesions [6]. In 1986, Ashizawa et al. reported one patient with ipsilateral leg monoparesis and four patients with ipsilateral arm monoparesis due to brain tumors or brain abscesses located in the contralateral superficial cerebral hemisphere [7], suggesting that monoparesis of the arm or leg due to brain damage was caused by a space-occupying lesion. Between the 1980s and early 1990s, several reports showed superficial infarctions presenting as PMM [8-13]. In 1997, based on a functional MRI study, cortical representation of the hand was determined to be located in the knob-like structure within the precentral gyrus (motor cortex), which was termed the precentral knob; that report also presented a case with hand monoparesis and sensory disturbance due to a precentral knob infarction [14]. Subsequently, numerous studies of hand PMM or monoparesis with sensory disturbances due to precentral knob infarctions were reported. Moreover, diffusion-weighted imaging (DWI), which provides accurate lesion location, led to more frequent reporting of PMM due to IS. In 2005, two large studies from Italy and Switzerland reported the frequency and lesion topography of PMM due to stroke [1, 2]. In 2011, the first English review of PMM due to IS was published from Japan [4].

PMM CRITERIA

Two large studies [1, 2] of PMM due to acute stroke outlined the criteria for PMM as follows: (1) first acute stroke (ischemic or hemorrhagic), (2) a motor deficit in a single body part (face, arm, or leg), (3) no sensory deficit (by subjective complaints and clinical examination), and (4) no visual field deficit. The criteria established by the second study are: (1) limb paresis without any sensory disturbance, coordination or language deficit, or significant involvement of speech or ipsilateral face, and (2) motor deficit caused by ischemic or hemorrhagic stroke, confirmed both clinically and radiologically. The criteria for distal arm PMM due to IS are isolated weakness of one arm or hand that is not associated with objective sensory, coordination, or language deficits, and no significant dysarthria or ipsilateral face or leg weakness [15]. Based on these criteria, PMM due to IS is defined as the presence of an isolated motor deficit in a single leg or arm with no sensory symptoms/disturbances or coordination deficits and no significant involvement of speech or ipsilateral face; the presence of a motor deficit caused by IS is confirmed both clinically and radiologically [4]. Brachiofacial motor stroke [16, 17] is excluded due to facial involvement. A number of previously reported cases of monoparesis due to IS had sensory disturbances, thus they do not fulfill the abovementioned current criteria for PMM due to IS. However, some reports of monoparesis due to IS, especially those with cortical infarctions, include both PMM and monoparesis with sensory symptoms and are often difficult to clearly distinguish. Some of these cases are described below.

FREQUENCY

The reported frequency of PMM due to IS is summarized in Table 1. Earlier studies using CT imaging did not always detect causative PMM lesions; thus, the exact frequency of PMM due to IS is difficult to assess [4]. Previous reports including PMM due to hemorrhagic stroke showed that PMM of the leg was rarer than that of the arm (14% vs. 86% [11], 28% vs. 72% [1], 33% vs. 67% [2]). However, one DWI study showed that the frequencies of leg and arm PMM were 54% and 46%, respectively, suggesting that leg PMM might not always be less common than arm PMM [4]. Most studies did not examine the differences in frequencies of arm and leg PMM as they primarily focused only on PMM cases involving the arm, focusing on precentral knob infarctions, and did not include leg PMM patients. Hemorrhagic stroke can also cause PMM [1, 2, 11, 13, 18-20], albeit at a lower rate than IS. As an example, Figure 1A shows traumatic intracranial hemorrhage presenting as leg PMM.

LESION TOPOGRAPHY AND CLINICAL FEATURES

IS of the cortical surface is more likely to cause PMM than deeper brain lesions, which frequently cause pure motor hemiparesis; this is due to the compaction of descending motor axons in a small area in the subcortex, internal capsule, and brainstem [4]. In this regard, cortical infarction of the hand motor area is the most frequent site affected by arm PMM, whereas cortical infarction of the anterior cerebral artery (ACA) territory is the most frequently reported site involved in leg PMM [1, 2].

Table 1. Reported frequency of pure motor monoparesis due to ischemic stroke

References	Year	Modality	Frequency and lesion locations
Nelson et al. [107]	1980	CT	1 (1 arm) of 26 pure motor stroke. Lesion: no visual lesion.
Donnan et al. [86]	1982	CT	1 (1 leg) of 69 pure motor stroke. Lesion: posterior limb of internal capsule.
Rascol et al. [85]	1982	CT	1 (1 leg) of 30 pure motor stroke. Lesion: internal capsule infarction widespread to putamen and caudate nucleus.
Weisberg [8]	1984	CT	4 (leg or arm is not described) of 40 patient with small superficial cerebrovascular lesion.
Arboix et al. [87]	1990	CT/MRI	8 (4 arm and 4 leg) of 227 patients with lacunar infarctions (8 of 125 pure motor stroke). Lesion: 1 of 8 had internal capsule (arm or leg is not described) 7 had no visual lesion.
Borten and Lodder [10]	1991	CT	7 (5 arm and 2 leg) of 252 patients with first-ever supratentorial ischemic stroke (2 had slight sensory disturbance). Lesion: 6 of 7 had cortical infarctions. 1 patient had no visual lesion.
Chimowitz et al. [105]	1991	CT/MRI	11 (leg or arm is not described) pure motor monoparesis of 81 patients with pure motor, sensorimotor, or pure sensory stroke (11 of 48 pure motor stroke). Lesion: this report showed no details of lesion topography.
Chamorro et al. [78]	1991	CT/MRI	2 of (2 arm) 337 patients with lacunar stroke (sensory disturbance of these 2 patients were not described).
Melo et al. [11] *	1992	CT/MRI	29 (25 arm and 4 leg) of 255 acute stroke patients.

				Arm lesion: deep infarcts 2, superficial infarcts 12, hemorrhagic stroke 1, and no visible lesion 10. Leg lesion: deep infarcts 1, superficial infarcts of ACA 2, no visible lesion 1.
Mohr et al. [12]	1993	CT	8 (all arm) cases of 183 with cerebral convexity infarction of the MCA territory. Lesion: mid-Rolandic region.	
Castaldo et al. [15]**	2003	CT/MRI	35 arm of 4818 ischemic stroke patients. Lesion: all had MCA territory infarction including parietal lobe.	
Maeder-Ingvar et al. [1]*	2005	CT/MRI	153 (123 arm, 30 leg) of 4802 stroke patients. Arm lesion: MCA 59%, subcortex 26%, brainstem 9%, ACA 2%, others 4%. Leg lesions: ACA 43%, subcortex 27%, MCA 23%, brainstem 7%.	
Paciaroni et al. [2]*	2005	CT/MRI	51 (34 arm, 17 leg) of 2003 stroke patients. Arm lesion: subcortical (corona radiata, centrum semiovale) 35.3%, cortical branches of anterior superficial MCA 26.5%, deep perforators of MCA 23.5%, thalamocapsular 8.8%, and cortical branches of posterior superficial MCA 5.9%. Leg lesion: cortical branches of the ACA 23.5%, watershed infarcts 17.6%, thalamocapsular 17.6%, striatocapsular 11.8%, pons 11.8%, subcortical (corona radiata, central semiovale) 5.9%, deep perforators of MCA 5.9%, and cortical branches of the anterior superficial MCA 5.9%.	
Celebisoy et al. [44]**	2007	MRI	7 hand of 815 patients who were hospitalized in the stroke care unit (this report did not described sensory symptoms). Lesion: posterior portion of the precentral gyrus.	
Alstadhaug and Sjulstad [40]***	2013	MRI/CT	13 hand of 866 ischemic stroke patients (15 had hand paresis and remaining 2 of 15 had sensory disturbance, not PMM). Lesion: this study was limited to hand motor area.	

CT, computed tomography; MRI, magnetic resonance imaging; ACA, anterior cerebral artery; MCA, middle cerebral artery.

*These studies included hemorrhagic stroke.

**These studies focused only on upper limb monoparesis, and the research criteria did not include leg monoparesis.

***This study focused only on hand paresis due to hand knob area infarction, and other topographies or leg monoparesis were not included. In this study, only one patient underwent CT, and the remaining patients underwent diffusion weighted imaging.

Note: 34 of 35 patients underwent MRI in the study by Castaldo et al. [15].

Table adapted from Hiraga [4].

Additionally, isolated distal, proximal, and distal-predominant monoparesis cases are observed more frequently in cortical PMM than in subcortical PMM. Selective damage to primary motor cortex results in restricted paresis of the contralateral upper and lower limbs in patients with cortical PMM. Pyramidal signs vary in each case but are relatively infrequently seen in both cortical and subcortical cases of PMM due to IS [4].

This table does not contain the study by Timisit et al. [21], which reported five patients with hand palsy among 690 patients hospitalized in the stroke care unit. All five had sensory disturbances. This table also does not include the study by Peters et al. [35] that was limited to hand knob area infarctions presenting with hand paresis and used diffusion-weighted imaging for all patients; they found that 29 of 3499 patients treated in the stroke care unit had hand paresis and that 22 of 29 patients showed isolated hand paresis. However, 10 of these 29 patients showed sensory disturbances; thus, the exact frequency of PMM was not determined.

Figure 1. Neuroimaging studies of patients with pure motor monoparesis (PMM) of lower extremities. (A) Computed tomography of a patient with PMM of the right leg due to traumatic intracerebral hemorrhage located in the left leg motor area. (B) Diffusion-weighted images (DWI) of a patient with PMM of the left leg due to acute cerebral infarction located in the right anterior cerebral artery (ACA) territory. (C) DWI of a patient with PMM of the right leg showing acute infarction located in the left ACA territory. This case presented with monoparesis restricted to the foot. (D) DWI of a patient with left leg PMM due to acute cerebral infarction located in the right central semiovale (D).

Cerebral Cortex

Arm

Superficial [8, 10, 13] and cerebral convexity infarctions (mid-Rolandic lesions) [12], infarctions of the anterior and posterior superficial middle cerebral artery (MCA) territories

[2, 11], and infarctions of the pial branches of MCA [9] have been reported as causes of upper limb PMM.

The areas affected in PMM or upper limb monoparesis due to cortical infarction are the precentral gyrus, especially the precentral knob, and the parietal lobe; the former is more frequently reported. One study reported six patients with isolated hand palsy due to IS of white matter of the angular gyrus [21]. All patients had sensory symptoms/disturbances, and one had aphasia; none fulfilled the criteria for PMM, suggesting that the parietal lobe was involved in motor control of the hand. Another study of 35 upper limb PMM cases reported that all patients had infarctions in the MCA territory [15]; nine of the 35 cases had some involvement of both the precentral and postcentral gyri, and 17 had some postcentral gyrus involvement. Importantly, all patients exhibited some involvement of the parietal lobe infarct, indicating that the parietal lobe was important for PMM development. The inferior parietal lobe may also be important in PMM [22].

Numerous studies showed precentral knob infarctions presenting as PMM or upper limb monoparesis [22-42]. Some reports found that the causative lesions were in the posterior portion of the precentral gyrus (i.e., the anterior bank of the central sulcus) [30, 32, 43, 44], whereas others indicated the frontal lobe, precentral gyrus [45, 46], or motor cortex [47]. Most studies showed that patients with upper limb PMM due to precentral gyrus infarctions had either distal or distal-dominant weakness, whereas several cases presented with proportional weakness [13]. In a study of 12 patients with predominant weakness in specific fingers and small cortical infarct, two of whom had PMM [29], MRI revealed that the lesions were related to predominant involvement of ulnar fingers and were located significantly more medially than those associated with predominant involvement of radial fingers in the presumed hand representation area of the motor cortex. These observations support traditional views [48], although individual variations in motor topography were also found [29, 31]. Others showed that ulnar or radial fingers were predominantly affected in monoparesis due to cortical infarctions [22, 23, 28, 30, 32, 43, 44, 46]. Furthermore, some studies indicated ulnar–medial and radial–lateral correlations [28, 32, 43]; patients with large lesions had uniform finger involvement [28]. Likewise, PMM due to cortical infarctions, mimicking radial or ulnar nerve palsy, a condition resulting from precentral knob infarction that imitates anterior interosseous nerve palsy, was also reported [37].

In 1999, Schieber and colleagues emphasized that they identified no cases with individual digit paresis due to IS in which the greatest weakness was in the index, middle, or ring fingers [43], providing little evidence that individual digits were represented in separate cortical territories; instead, these findings suggested broadly overlapping (i.e., lateromedial) gradients in the cortical representation of radial and ulnar fingers. Although cases with isolated thumb [34] or index finger paralysis [31, 41] and those with isolated ring finger palsy [38] due to precentral knob infarctions were reported, there are no reported cases with isolated middle finger or little finger PMM due to IS. However, predominant thumb weakness was noted in some cases; one patient with significant thumb weakness during the recovery phase of hemiparesis exhibited predominant thumb flexion weakness [49], whereas another patient with isolated fingers weakness due to precentral gyrus infarction had predominant thumb weakness wherein thumb adduction and flexion were strongly affected [23]. These two cases, in addition to an isolated complete thumb paralysis case [34], provide supporting evidence that motor hand areas might contain a subregion that selectively represents the thumb [43]. Moreover, two previously reported cases with isolated index finger weakness [31, 41] and

one patient with prominent index finger weakness sparing the thumb and largely sparing the ulnar fingers [33] suggest the presence of a subregion selectively representing the index finger.

Although most cases of upper limb PMM due to cortical infarctions present with distal-dominant weakness, cases of isolated shoulder paresis were also reported [4, 50-54]. The first reported isolated shoulder PMM case in 2003 had an infarcted region restricted to the base of the central sulcus and in the deep white matter, located midway between the precentral knob and longitudinal cerebral fissure [50]. One patient with an isolated shoulder seizure due to a small cortical infarction had a lesion in a similar region [55], indicating that this location correlated with human shoulder motor somatotopy. Cases with PMM limited only to shoulder and arm muscles also had precentral gyrus infarctions in the precentral gyrus, medially to the precentral knob [56]. Although patients presenting with an affected wrist flexor were also diagnosed with PMM [25], predominant wrist extensor involvement was more frequently observed [26, 27, 44]. Furthermore, not many differences between finger extensors and flexors occur with precentral knob infarctions, except for mild differences observed in some cases [30, 44]. Deep tendon reflexes (DTRs) of the affected limb in PMM cases with precentral knob infarction were either normal or symmetric in some patients [22, 27, 37]. In particular, normal or symmetric DTRs were evident in patients with weakness in isolated or specific fingers [25, 31, 33, 34], as well as in those with isolated shoulder weakness [50, 51, 53]. However, several patients exhibiting weakness in specific fingers [29] and one patient with isolated shoulder palsy [54] had active DTRs of the affected limb. Other case reports also showed active or brisk DTRs [24, 28, 42, 43]. The Babinski sign was negative in most cases; thus far, only one case presenting with a positive Babinski sign has been reported [22]. In one study on cortical infarction presenting as arm PMM, patients demonstrated all DTR patterns: symmetrical, active, or decreased [13]. A case of claw hand deformity in acute stage of PMM due to hand knob area infarction mimicking peripheral nerve disease has been reported [42], although the majority of stroke-associated PMM cases did not exhibit any hand deformities in the acute stage. The differences in PMM and monoparesis with sensory disturbances might partially be due to postcentral gyrus involvement, as those with infarct regions involving both the precentral and postcentral gyri had sensory symptoms [25, 32]. Figures 2A and 2B show a patient with precentral knob infarction presenting as isolated hand PMM. Figure 2C shows a patient with radial-dominant hand PMM due to a precentral knob infarction, and Figure 2D shows a patient with proximal-dominant upper limb PMM due to cortical infarction.

Leg

Cortical branches of the ACA are the most common sites affected in leg PMM [2]. Classically, leg-predominant weakness due to stroke results from ACA territory infarctions and consequent paracentral lobule involvement [57]. Leg PMM due to cortical infarctions occurs in the precentral gyrus [58-67], paracentral lobe [68-73], and supplementary motor area [74]. Other small cortical infarctions in the ACA territory were also reported [10, 11]. Although the details of infarcts were not described, four patients with leg PMM due to occlusion or severe stenosis of internal carotid artery were reported [75].

The weakness patterns of leg PMM due to ACA territory infarctions can be proportional [68, 69], distal-dominant [59-62, 64-67, 72, 74], or proximal-dominant [59, 63, 73]. The rear portion of the medial precentral gyrus is the site affected in distal-dominant weakness [59].

One patient was reported to develop isolated toe paralysis in the recovery phase of a paracentral lobule infarction [72]. Additionally, several cases presenting with isolated foot drop due to precentral gyrus infarctions were reported [62, 64-67, 74]. These reports indicate that a small ACA territory infarction may cause isolated distal leg PMM. Some patients were reported to exhibit active DTRs of the affected leg [60,64,69], whereas normal or symmetric DTRs were observed in other cases [61-68, 72-74]; one patient with a decreased DTR was also reported [61]. A positive Babinski sign on the affected side was demonstrated in several cases [64, 69, 72, 73], whereas it was negative in others [60-65, 67, 74]. Figures 1B and 1C show ACA territory cortical infarctions presenting as leg PMM; the case illustrated in Figure 1C presented with isolated foot paresis.

Figure 2. Neuroimaging studies of patients with pure motor monoparesis (PMM) of upper extremities. (A) Diffusion-weighted images (DWI) of a patient with PMM of the left hand due to an acute cerebral infarction located in the hand motor area. (B) Fluid-attenuated inversion recovery images showing an infarction of the same area. (C) Computed tomography of a patient with PMM of the right hand. This case presented with predominant involvement of radial fingers, and the affected region was located in the lateral region of the presumed hand representation area of the left motor cortex (precentral knob). This case indicated ulnar-medial and radial-lateral correlations. (D) DWI of a patient with proximal dominant-PMM of the right upper extremity, showing an infarction located in the left precentral gyrus medial to the knob-like structure, and laterally to the shoulder motor area. Arrows indicate the contralateral precentral knob.

Subcortex, Centrum Semiovale, and Corona Radiata

Although some patients with cortical infarctions presenting as PMM also had adjacent subcortical regions that were infarcted, a subcortical infarction without affected cortical regions can also lead to arm or leg PMM. A large study showed that 26 patients with arm PMM and 27 patients with leg PMM had subcortical infarctions [1]. Another large study showed that ten patients with subcortical (corona radiata or centrum semiovale) infarctions had PMM; most cases had PMM of the arm [2]. A report on subcortical infarctions of the superficial MCA territory affecting the centrum semiovale showed that 2 of the 36 patients had upper limb monoparesis [76]. Other reports presented cases with frontal subcortical infarctions in the ACA territory that presented as leg PMM [68, 77]. A case report showed that brachial monoparesis in a patient was due to a corona radiata infarction [78]. Another study including eight arm PMM and six leg PMM patients [79] noted that patients with leg PMM had more posteriorly and medially located infarct regions than those with bulbofacial paresis or arm PMM, indicating anterolateral to posteromedial distribution. Other studies also indicated anteroposterior somatotopy in the corona radiata; leg fibers were located more posteriorly than arm fibers [68, 80, 81]. One diffusion tensor tractography (DTT) study showed that the hand fiber tract was located in the anteromedial portion of corona radiata [82], while another DTT report demonstrated that hand somatotopy of the corticospinal tract (CST) was located anterolaterally to the leg somatotopy of the CST in central semiovale [83]. These DTT findings and PMM case studies indicate that hand fibers are located more anteriorly than leg fibers and that anterior corona radiata infarction might manifest as hand PMM. PMM involving one or more fingers due to subcortical infarction was rarely reported. However, a patient with palsy of only ring and small fingers due to a subcortical infarction was reported [84]. Moreover, another patient had profound weakness and decreased sensation in the thumb and index finger due to a corona radiata infarction [46]; this patient was not diagnosed with PMM due to accompanying sensory disturbances. However, these observations indicate that involvement of specific fingers can occur not only due to a cortical infarction, but also due to a subcortical or corona radiata infarction, suggesting finger somatotopy might also exist in the subcortical region.

Patients with ACA territory subcortical infarctions and distal-dominant [77] or proportional [68] weakness were reported to have normal DTRs. Additionally, cases with leg PMM due to corona radiata infarctions had proportional weakness with brisk or normal DTRs of the affected leg [68]. Figure 1D shows a subcortical infarction presenting as leg PMM.

Internal Capsule

A CT study showed that leg PMM could result from an internal capsule infarction spreading to the putamen and caudate nucleus [85] or from an infarction located just lateral to the posterior limb of the internal capsule [86]. In another report, PMM due to an internal capsule infarction was detected by MRI [87], although it was not clear whether the arm or the leg was affected. Yet another report suggested that isolated arm monoparesis might also be due to infarction of the internal capsule [78]; however, no information was enclosed regarding sensory disturbances in that study. Other cases involving infarction of the posterior limb of the internal capsule presenting as leg PMM were also reported [59, 68]. Moreover, one report described a patient with infarction of the posterior limb of the internal capsule who developed an abrupt fall but showed only unilateral pyramidal tract signs in lower extremities during neurological examination [88].

A previous large study on monoparesis found that internal capsule infarctions, either striatocapsular or thalamocapsular, led to leg PMM in a small number of patients [2]. Traditionally, the somatotopic CST organization in the internal capsule is a homunculus, i.e., the hand fibers are located more anteriorly and slightly medially to the foot fibers. However, considerable overlap was demonstrated between hand and foot fibers [89]. A linear infarction along the long axis of the internal capsule was characteristic of posterior limb internal capsule infarction presenting as leg PMM [68]. These two cases support the results of an MR tractography study [90, 91], which demonstrated that CST foot fibers in the posterior limb of internal capsule might be somatotopically posteromedial to the hand fibers along the short axis of internal capsule. However, other studies showed that hand fibers were located anteromedial to foot fibers in the posterior limb of internal capsule [82, 92].

Clinically, two reported cases with leg PMM due to internal capsule lesions had slight proximal-dominant weakness with no Babinski sign and normal DTRs [68], whereas a separate patient had proportional leg weakness [59].

Brainstem

An acute brainstem infarction is difficult to detect by CT; thus, few brainstem infarctions presenting as PMM by CT were reported. One earlier CT study presented a patient with arm PMM due to a pontine infarction [93], whereas a larger study showed only two leg PMM cases resulting from pontine infarctions, with no patients presenting exhibiting arm PMM [2]. Another study showed nine arm PMM and seven leg PMM cases due to brainstem infarctions [1]. Distal-dominant brachial monoparesis results from infarction of the ventromedial pontine base on DWI, indicating that arm fibers are located more medially than leg fibers [94]. Rostral lateral pontine infarction presenting with leg PMM in three patients [95] indicated that the lesions responsible for crural monoparesis were presumably located in the dorsal and lateral regions of pontine base. Another study indicated that the lesions in PMM patients with leg-predominant weakness were dorsal and lateral in the pons [59]. The regions for pontine infarctions that did not present with PMM were located in the ventromedial region in patients with lower predominant hemiparesis, and were correlated with lesions in the dorsomedial and dorsolateral portions in patients with upper predominant hemiparesis [80], whereas the upper extremity fibers were located more ventromedially than the lower extremity fibers in four patients with brachial monoparesis and dysarthria due to pontine base infarctions [96]. A voxel-based MRI analysis of the basilar pons [97] indicated that upper extremity weakness was correlated with specific pontine regions; however, another study [98] did not show significant topographical differences between patients with paresis predominantly affecting the arm or leg, suggesting that the topographical arm/leg distribution was disrupted in the pons and that PMM due to brainstem infarctions was rare. However, DTT studies indicated the presence of motor somatotopy of the hand and leg in the brainstem. Specifically, hand somatotopy of the CST is located in the anteromedial portion of pons and leg somatotopy of the CST is located posterolateral to hand somatotopy of the CST [82, 99]. Additionally, hand somatotopy of the CST is located in the medial portion of the medullary pyramid, whereas leg somatotopy of the CST is situated in the lateral portion of the medullary pyramid [100]. The case report also suggests that the CST fibers innervating lower and upper extremities decussate at different levels in the lower medulla oblongata [101].

PMM due to midbrain or medulla infarctions is extremely rare. There are several case reports of patients with cerebral peduncular or medial medullary infarction presented with

monoparesis; however, these cases either had accompanying sensory symptoms or did not have detailed description of symptoms [59, 102, 103]. One Japanese study reported a patient with PMM due to a medullary infarction that was limited to the upper lateral region of medullary pyramid [104]. PMM due to lateral medullary infarction was also reported by a group from Japan [101].

Assessment of clinical features reveals that patients with arm PMM due to pontine infarctions develop proportional weakness with normal DTRs [93] or distal-dominant arm weakness with active DTRs [94], both in the absence of a Babinski sign. Among patients with leg PMM due to rostral lateral pontine infarctions, two cases with dorsolateral infarcts were proximally dominant, and one case with an anterolateral infarct had proportional weakness [95]. One patient with a medullary infarction presenting as leg PMM showed proportional weakness with active DTRs [104], and two patients with leg PMM due to medullary infarctions had a positive Babinski sign in the affected leg [101, 104].

MECHANISMS OF STROKE IN PMM

PMM frequently occurs following cortical infarctions, and findings from earlier reports suggest that PMM rarely results from lacunar infarctions [11, 13, 105]. Eleven patients with leg or arm monoparesis revealed that the etiology of stroke was occlusive large artery disease and cardioembolism in six and three cases, respectively; the cause was either undetermined or miscellaneous in the remaining two patients [105]. Melo et al. reported 28 patients with PMM due to IS; the causes were determined as deep infarcts in 3 patients, superficial infarcts in 14 patients, and no visible lesions in 11 patients [11]. In contrast, a large study indicated that the etiologies of PMM due to IS were small artery disease, cardioembolism, and atherosclerosis in 39.2%, 15.7%, and 9.8% of patients, respectively [2], suggesting that small artery disease was the most likely cause of PMM. Another large study found no particular etiology in arm or leg monoparesis subgroups [1].

A study of seven patients with superficial infarctions and monoparesis (leg, 2; arm, 5) revealed cardioembolism as the cause in two cases; however, neither had significant carotid stenosis [10]. Another report showed that, out of 14 patients, arm PMM or monoparesis due to IS resulted from carotid pathology and cardioembolism in six and four cases, respectively [13]. In studies that found a correlation between upper limb monoparesis and parietal lobe infarction, all six patients had infarctions in the vascular border zone of angular gyrus white matter; five of these six cases had carotid stenosis, suggesting a hemodynamic mechanism [21]. Others showed that cardiac sources were the most frequent etiologies: cardioembolism/cardiac source in 46%, large artery atherosclerosis/carotid stenosis in 34%, MCA branch thrombosis in 17%, and cryptogenic in 3% [15]. In a study of 11 patients with distal arm PMM due to cortical infarctions, three had a patent foramen ovale, three had carotid stenosis, and two had cardiac arrhythmias; one of the latter also had MCA stenosis [28]. A study of six patients with isolated upper limb weakness due to cortical infarction reported cardioembolism, large-artery atherosclerosis of the MCA, and undetermined etiology in one, two, and three cases, respectively [22]. In a report of 29 precentral knob infarctions (22 of 29 patients showed isolated hand paresis, and 10 of 29 patients showed sensory disturbance), ten patients had carotid stenosis, whereas four were found to have a cardiac

embolic source [35]. These results indicated that precentral knob area infarctions were frequently associated with atherosclerotic changes in the carotid artery and suggested an arterioarterial thromboembolic stroke mechanism. Yet in another study of seven patients with arm PMM due to precentral gyrus infarctions, the mechanism of stroke was determined as large artery atherothrombosis (internal carotid artery stenosis, 2 cases), cardiogenic embolism (2 cases), secondary to hypoperfusion (1 case), and undetermined in (2 cases) [39]. A recent large study including patients with hand PMM due to knob infarctions had 15 patients with hand palsy, two of whom had sensory disturbances. In that study, stroke etiologies were large artery atherosclerosis in three patients, cardioembolism in two patients, small artery disease in five patients, and unknown in five patients [40]. Kim proposed that the motor cortex region representing ulnar fingers might be a border zone between large arteries. The author suggested that predominant involvement of ulnar fingers due to cortical infarctions was closely associated with severe proximal arterial stenosis or occlusion of the MCA or internal carotid artery and that predominant involvement of radial-sided fingers was often related to emboligenic stroke [29]. Other case reports showed carotid stenosis [34, 36, 45] or cardiogenic embolism [31, 37] as underlying stroke etiologies in PMM patients. One case report showed that hypotension might either cause or contribute to the precentral knob infarction in a patient with hand PMM [26]. The first reported isolated shoulder palsy due to a small cortical infarction with severe carotid stenosis was reported as a border-zone infarction [50]. In fact, proximal arm weakness has traditionally been considered a manifestation of border-zone infarction. However, subsequent isolated shoulder palsy cases due to cardiogenic embolism [51, 54] and atherothrombosis [52, 53] indicated that the mechanism of stroke in arm PMM due to cortical infarction might include both cardioembolic and carotid sources, which underlies the difficulty in determining the more frequent etiologies in these clinical entities. Rare etiologies reported by several groups include aortogenic embolism [41] and cerebral angitis [42] presenting as precentral knob infarctions and PMM.

One study including six patients showed that the mechanism of leg PMM due to small ACA cortical infarctions was cardiac embolism in three cases; the etiology was unknown in the remaining three patients [64]. Other reports also showed carotid stenosis or carotid emboli [8, 59, 63, 73], ACA stenosis [67], and cardiogenic embolism [59, 68] as causes of leg PMM due to ACA cortical infarctions. One study showed that the majority of leg PMM cases were correlated with occlusion or severe stenosis of the internal carotid artery [75]. Additionally, a large study showed that watershed infarctions were found only in patients with leg PMM but not in those with arm PMM [2].

Centrum semiovale infarcts with upper limb monoparesis were reported to result from small vessel disease [76]. Furthermore, lacunar infarctions of the internal capsule were reported to cause PMM [59, 86, 87]. Small artery disease might be the most frequent mechanism for brainstem infarctions [94, 95]; however, it can also result from vertebral artery occlusion [101].

DIFFERENTIAL DIAGNOSIS

As described above, either the radial or ulnar side can be predominantly affected in cortical hand PMM, raising the possibility of misdiagnosis of these patients with cervical disc

disease or radial or ulnar neuropathy [5]. It is critical to include cerebral lesions in the differential diagnosis of monoparesis. Following are the important points for a successful diagnosis of PMM due to IS [4]: (1) *Anamnesis*. Typically, mononeuropathy, such as radial nerve palsy, has a preceding compression event; thus, sudden or acute onset of weakness in one hand without history of a compression event might be an indicator of PMM due to IS. (2) *Risk factors for cerebrovascular disease*. The presence of hypertension, diabetes mellitus, atrial fibrillation, and/or hyperlipidemia is also important. (3) *Pyramidal signs*. DTRs are often decreased and no pathological reflexes are present with peripheral nervous system damage. Therefore, DTRs and muscle tone are important tools to distinguish central and peripheral weakness. However, PMM due to IS does not always show active DTRs in the affected limbs. In fact, there is a relatively low frequency of active DTRs in both arm and leg PMM cases resulting from IS [13, 68], and the absence of pyramidal signs should not exclude PMM due to IS. (4) *The distribution of weakness*. Patients with PMM due to IS show frequent distal-dominant weakness, and some have radial or ulnar finger-predominant weakness. In these patients, the affected muscles are not completely the same as the peripheral nerve distribution, and careful neurological evaluation is necessary. (5) *Neuroimaging*. DWI is the most useful tool for diagnosis, as CT and conventional MRI cannot distinguish between acute and chronic lesions. In fact, 11 of 28 patients with PMM due to IS had no visible lesions by CT or conventional MRI [11], and all eight patients with PMM in one study showed no visible lesions on repeat CT scans [87]. In a study of distal arm PMM patients, 77% of the 35 patients demonstrated no causative lesions on their first CT scans [15]. Without the use of DWI, small cortical infarctions as well as acute infarctions might be overlooked or misidentified. The recommended MRI sequences include DWI for acute ischemia, fluid-attenuated inversion recovery, T2*-weighted gradient-echo images for bleeding, and MR angiography.

PROGNOSIS

A large study in 2005 showed that 41% of PMM patients returned to their former activities and that 41% of patients required some assistance, indicating that outcomes of PMM are generally favorable [1]; however, isolated facial paresis and hemorrhagic stroke were observed in some patients. Therefore, the exact outcomes of PMM due to IS remain unclear.

Some case reports on cortical infarctions presenting as arm PMM described improvements [14, 24, 42, 56]. While most studies did not evaluate the prognosis of PMM due to IS [8, 11, 12, 25, 27, 32, 36, 38, 43, 44, 50], others determined good or complete recovery in patients with PMM due to IS [10, 15, 22, 23, 26, 28-31, 33-35, 37, 41, 45, 46, 51-53, 106]. For example, one study determined that 14 of the 35 patients with arm PMM due to cortical infarctions had complete clinical recovery, albeit residual mild weakness was reported in 21 patients [15]. Yet another report showed that all patients with PMM had complete recovery within 2–4 weeks [10]. Furthermore, several case studies showed a high frequency of complete recovery [22, 28, 35]. Finally, patients exhibited good recovery despite the presence of severe finger weakness at initial examination [23, 29, 34, 37, 45].

The rate of recurrent stroke in PMM due to IS has not been established; however, several studies examined outcomes in patients with PMM of the arm. Specifically, one report on arm PMM due to cortical infarction showed a 14% rate of recurrent stroke (mean follow-up, 1.7 years) [15], whereas another study of seven patients with arm PMM due to cortical infarctions with a mean follow-up of 14 months showed two patients had stroke recurrence. The second study also reported the death of one patient; the remaining four cases had excellent recovery with no recurrence [39]. A recent study of 15 patients with knob infarctions, of which 13 had PMM and 2 had monoparesis with sensory disturbances, had a mean follow-up period of 29.8 months [40]. While none of the patients had recurrence, one patient died, and two patients had bad recovery; the hand function was good and fair in six and eight cases, respectively [40]. In some studies, patients with PMM underwent carotid endarterectomy for carotid stenosis [15, 34, 36, 45]. Finally, patients with isolated shoulder PMM due to cortical infarction were reported to have good recovery [51-53]; however, in one study, one patient died on day ten [54].

In a study of cortical ACA infarction cases presenting with lower limb PMM, two of the three patients with proximal weakness had good clinical recovery, whereas the only patient with distal weakness had poor recovery [59]. A separate report showed that five of the six patients with distal leg PMM had partial or complete clinical recovery [64]. Other studies reported recoveries ranging from complete [62, 66] to good [70, 72] or improved [60, 61, 63, 65, 67, 69, 74]. One patient with a subcortical infarction had a good prognosis [77]. Prognoses have not been described for patients with subcortical, centrum semiovale, or corona radiata infarctions presenting as PMM. Patients with pontine infarctions presenting as PMM can have good recoveries; three cases with leg PMM due to rostral lateral pontine infarctions showed good functional recovery [95], and one case with brachial PMM due to a pontine infarction showed a complete recovery [93]. Furthermore, gradual improvements or complete recovery were observed in other cases with brachial PMM due to pontine infarctions or with leg PMM due to medullary infarctions [94, 101, 104].

In summary, previous studies have indicated a good prognosis for patients with arm PMM due to cortical infarctions, especially those in the precentral knob. Due to their rarity, the outcomes of patients with PMM due to infarctions in other regions are difficult to discuss; however, most reported cases had good clinical recoveries. Ultimately, both short- and long-term outcomes depend on risk factors and stroke mechanisms [40].

FURTHER INVESTIGATION

The history of studies about PMM due to IS provides anatomical evidence regarding motor cortical representations in human cortex and differences between motor fiber pathways of the arm and leg; however, some anatomical questions remain debatable. Tractography studies were not always consistent with clinical experiences in patients with PMM due to IS. Although some individual variation exists, it is unclear whether motor somatotopy of the arm and leg clearly exists or breaks down in the deeper regions, especially the brainstem. Moreover, whether individual fingers are represented in a separate cortical territory with overlap should be reexamined as certain case reports indicated that isolated thumb, index

finger, or ring finger palsies could be the sole manifestation of cortical infarction [4]. Finally, individual motor somatotopy of the toe was not well understood until now.

Despite its importance, PMM due to IS remains underestimated. In recent years, it has been increasingly reported by neurologists who recognize and understand this atypical stroke syndrome. However, orthopedists and general clinicians are mostly unaware of this condition, and neurologists should alert physicians to its presence. Two large studies from 2005 were hospital-based research and did not use MRI, especially DWI, in all patients. Moreover, the percentage of patients who had PMM in those studies was probably smaller than the general population as patients with very minor motor deficits are less likely to be admitted to a hospital [2] or are misdiagnosed with nonvascular causes of weakness. Additionally, the assumption that lacunar etiology is not likely a cause of PMM due to IS should be reexamined [2]. The exact frequency of PMM due to IS, its clinical features such as paresis pattern, DTR, and the presence of Babinski sign, and prognosis, especially the recurrent stroke rate, should be examined in a large study by a national survey, using DWI for all cases.

STROKE ASSOCIATED WITH NEPHROTIC SYNDROME - ACUTE ISCHEMIC STROKE, CEREBRAL VENOUS SINUS THROMBOSIS, AND INTRACEREBRAL HEMORRHAGE

Masaru Kuriyama, MD, PhD

Department of Neurology, Brain Attack Center Ota Memorial Hospital, Fukuyama, Hiroshima, Japan

ABSTRACT

Nephrotic syndrome is defined by the presence of heavy proteinuria, hypoalbuminemia, hyperlipidemia and peripheral edema. Thrombotic diseases are also frequently observed. Arterial and venous thromboses are potential complications of nephrotic syndrome. Arterial thromboses are less frequent than venous thromboses and the most common locations are femoral arteries, although other arteries may be involved. Stroke associated with nephrotic syndrome has been reported in a number of case reports, but it is rare and its clinical details remain obscure. We identified ten cases of acute ischemic stroke, two cases of cerebral venous sinus thrombosis, and four cases of intracerebral hemorrhage by screening the hospitalized patients enrolled in our stroke unit. The incidence of acute ischemic stroke associated with nephrotic syndrome was 0.09% of all kinds of stroke and 0.12% of acute ischemic stroke, and was fivefold that of cerebral venous sinus thrombosis. The subtypes of stroke identified in our screening were large-artery atherosclerosis (six instances), small-vessel occlusion (three instances), and cardioembolism (one instance). The results of a retrospective cohort study showed that acute ischemic stroke-associated nephrotic syndrome is strongly associated with atherosclerosis of the cerebral artery, especially in the anterior circulation. Patients also exhibited atherosclerosis of the internal carotid and lower extremity arteries. The causal disorder of nephrotic syndrome was diabetic nephropathy in eight of these cases. Twenty-five patients with cerebral venous sinus thrombosis were admitted to our hospital during the same period. Nephrotic syndrome has been reported to be responsible for 0.6-1.0% of all cases of cerebral venous sinus thrombosis; however, our study showed that this percentage may be higher. Nephrotic syndrome essentially induced a hypercoagulable state. However, four cases of intracerebral hemorrhage associated with nephrotic

syndrome were identified by the screening. These exhibited the presence of strong risk factors for hemorrhage, including hypertension, vascular vulnerability with atherosclerosis or amyloidosis, and change of bloodstream after operation, suggesting that they overcame the risk for thrombophilia. The diseases associated with nephrotic syndrome were diabetic nephropathy and amyloidosis in three cases and one case, respectively. Nephrotic syndrome tends to be associated with a risk for arterial or venous thrombosis. In addition, we must pay attention to intracerebral hemorrhage associated with nephrotic syndrome in cases of stroke.

1. INTRODUCTION

Nephrotic syndrome (NS) is defined by the presence of heavy proteinuria (protein excretion greater than 3.5 g/24 hours), hypoalbuminemia (less than 3.0 g/dL), hyperlipidemia, and peripheral edema [1] (Figure 1). Thrombotic diseases are also frequently observed. Arterial and venous thromboses are potential complications of NS. Arterial thromboses are less frequent than venous thromboses, and the most common locations are femoral arteries, although other arteries may be involved [1-3]. Acute ischemic stroke (AIS) associated with NS has been reported in several case reports [4-10], but this is relatively rare.

Cerebral venous sinus thrombosis (CVT) is less common than most other types of stroke, but is recognized with increasing frequency due to the widespread use of magnetic resonance imaging (MRI) and rising clinical awareness. The clinical severity varies, and severe sequelae can occur when treatment is delayed. In some cases, death may occur from brain herniation due to increased intracranial pressure; therefore, quick and accurate diagnosis is required.

Figure 1. Clinical symptoms in nephrotic syndrome.

As CVT is also caused by various underlying diseases, it is important to analyze the causative disorders [2, 11, 12], as well as the immediate treatment for thrombosis. In the past, CVT was attributed to infections of the face and otomastoid areas, but since the introduction of antibiotics, it is more often related to pregnancy, puerperium, neoplasms, dehydration, genetic or acquired thrombophilia, and oral contraceptives [2, 11-13]. In Western countries in particular, CVT is increased by the hypercoagulability induced by oral contraceptive use [14-16]. NS is one of the risk factors for CVT. With recent increases in the number of patients with NS, it is likely that the number of patients with CVT caused by NS will increase, especially in Japan.

Hypercoagulability contributes to the predisposition to thromboembolism in NS. The low molecular weight coagulation factors (Factor IX, XI), antithrombin III, plasminogen, and free protein S excreted into the urine by the breakdown of the permselectivity barrier of the glomerular capillary wall have been reported, along with inverse increases in high molecular weight coagulation factors (Factor V, VII, VIII and X), fibrinogen, alpha 2-antiplasmin, alpha-2-macroglobulin and platelet aggregation [16-23]. These changes have been attributed to a hypercoagulable state in which an imbalance between procoagulant/prothrombotic factors and anticoagulant/antithrombotic factors promote thromboses in veins and arteries. Hypoalbuminemia, secondary volume depletion, and hyperlipidemia also could act as risk factors for thromboembolism or atherosclerosis. NS may independently predispose individuals to arterial and venous thromboembolism, but the exact mechanism of the hypercoagulability is as yet not fully understood [1-4, 16-23].

Hypercoagulability due to NS involves the pathogenesis of AIS or CVT. When we retrospectively screened stroke patients with NS from hospitalized patients enrolled in our stroke registry, it was found not only in those patients with AIS and CVT, but also, unexpectedly, in some patients with intracerebral hemorrhage (ICH) [24-26]. These patients had strong risk factors for ICH, suggesting that they had overcome the risk for thrombophilia. Attention should be paid to NS as a risk factor for stroke including AIS, CVT, and also ICH.

2. SCREENING FOR STROKE PATIENTS WITH NS

We retrospectively analyzed 11,161 cases of hospitalized patients enrolled in our stroke registry during a nine-year period from April 2004 to August 2013. The number of patients with serum albumin lower than 3.0 g/dl was 196 (1.9%) out of 10,057 patients examined, and that of patients with serum cholesterol higher than 250 mg/dl was 1,201 (11.3%) of 10,619 patients examined. The patients with albumin below 3.0 g/dl and serum cholesterol above 250 mg/dl at the same time were screened, and only 21 cases fulfilled both levels. From these patients, furthermore, the cases showing heavy proteinuria were selected. The proteinuria was estimated quantitatively by measuring the protein in a urine/24 hours or qualitatively by using a paper kit (Eiken Chemical Co. Japan) (Figure 2). They included two cases showing negative or equivocal ($\pm$) results in the protein paper kit test, one case with 1+ (30 mg/dl), two cases with 2+ (100 mg/dl), five cases with 3+ (300 mg/dl), and 11 cases with 4+ (1000 mg/dl). The 16 patients showed urinary protein 3+ or 4+ - i.e., heavy proteinuria - and comprised 10 patients with AIS, four with intracranial hemorrhage, and two with cerebral venous thrombosis (CVT) (Table 1). Nine of these 16 patients showed protein excretion greater than

3.5 g/24 hours. In the other seven patients, the content of protein in urine/24 hours was not measured. However, they all had moderate to severe peripheral edema and hyperlipidemia, and the diagnosis of NS was also strongly suggested in these seven cases.

Proteinuria: measured quantitatively by measuring the protein in a urine/24 hours or qualitatively by using paper kit (Eiken Chemical Co. Japan).

Figure 2. The screening and selection of the stroke patients with nephritic syndrome.

Table 1. The patients of acute stroke

	TIA	SVO	LAA	CE	other	ICH	SAH	Total

① + ② + ③	0	3	6	1	2 (CVT)	4	0	

Abbreviations: TC – total cholesterol; Alb – albumin; UP – urinary protein; TIA – transient ischemic attack; SVO – small-vessel occlusion; LAA – large-artery atherosclerosis; CE – cardioembolism; ICH – intracerebral hemorrhage; SAH – subarachnoid hemorrhage; CVT – cerebral venous sinus thrombosis.

3. ACUTE ISCHEMIC STROKE (AIS) ASSOCIATED WITH NS

1) AIS Patients

The 10 cases – eight males and two females, 64.4 ± 8.6 yrs (Mean $\pm$ SD) – were diagnosed as AIS associated with NS. The incidence rate was 0.09% of all kinds of stroke (total 11,161 patients) and 0.12% of AIS (total 8,116 patients) in our hospital. Of these ten cases, six were of large-artery atherosclerosis (LAA), three of small-vessel occlusion (lacune, SVO), and one of cardioembolism (CE) by the TOAST criteria. On MRI and MRA, middle cerebral arteries, anterior choroidal artery, and internal carotid artery (occlusion) were

involved in six cases, one case and one case, respectively. SVOs were located in the supratentorial basal ganglia in all three of the SVO cases (Table 2). NS had not been diagnosed prior to admission in any of the 10 cases. Pathological diagnosis was arrived at through histopathological examination of the renal biopsied samples in two cases; amyloid nephropathy due to primary amyloidosis in one case, and membranoproliferative glomerulonephritis (MPGN) in one case. Eight cases were diagnosed as diabetic nephropathy (DMN) based on the long history of diabetic mellitus (DM) and the exclusion of other pathogenetic diseases, although renal biopsy was not performed (Table 2).

Table 2. The patients of acute ischemic stroke with nephrotic syndrome

Case	Age	Sex	Type	MRI Location of infarction	Alb	TC	UP	day	E	DM Duration (years)	NS type
1	50	F	LAA	R. MCA (BAD)	3	284	4	8.4	++	15	DN s/p

9	69	M	SVO	R. Basal Ganglia	3	299	3		++	4	DN s/p
10	69	M	CE	R. MCA	3	264	4		++	8	DN s/p

Abbreviations: TC – total cholesterol; Alb – albumin; UP – urinary protein, E – edema; SVO – small-vessel occlusion; LAA – large-artery atherosclerosis; CE – cardioembolism; L – left; R – right; MCA – middle cerebral artery; BAD – branched atheromatous disease; Ant – anterior; Choro. – Choroidal; IC – internal carotid; NS – nephrotic syndrome; DN – diabetic nephropathy; MPGN – membranoproliferative glomerulonephritis; AMN – amyloido nephropathy.

2) Arterial Stenosis in the Patients

Extent of atherosclerosis was evaluated by the atherosclerosis score of intracranial and extracranial arteries on MRA [27]. A total of 17 vessels – including the common carotid arteries, the extracranial and intracranial portions of the internal carotid arteries and the vertebral arteries, the anterior, middle, and posterior cerebral arteries, and the basilar artery – were evaluated by the cervical and intracranial MRAs. The individual total scores were divided into two scores: an anterior score and a posterior score, related to the anterior circulation vessels (common carotid, internal carotid, anterior cerebral, and middle cerebral arteries) and posterior circulation vessels (vertebral, basilar, and posterior cerebral arteries), respectively.

Ultrasonography of carotid arteries and lower extremities arteries was performed and the stenotic lesions of these arteries graded. The atherosclerosis of lower extremity arteries were also evaluated by measurement of ankle-brachial index (ABI). A total carotid ultrasonic score (T-CUS) and total extremities ultrasonic score (T-EUS) were estimated as the sum of the right

and left ultrasound score grades for the carotid and extremity arteries, respectively. A total ABI (T-ABI) score was estimated as the sum of the right and left ABI.

We carried out a retrospective cohort study to assess the association between NS and atherosclerosis progression. AIS patients with NS due to DMN were compared with AIS patients without NS. Cases were compared with controls in respect of body mass index (BMI), morbidity of hypertension, and several laboratory findings. Case 2 with amyloid nephropathy, case 7 with MPGN, and case 10 with CE, were excluded from this study. The remaining seven patients with AIS and NS due to DMN were selected as cases (NS group). Cases were compared with AIS patients with DM without NS (control group) who were matched to cases in a 2:1 ratio by age, sex, use of medications for DM, and HbA1c level. The control group included 11 cases with SVO and three cases with LAA, and had a larger number of SVOs than that of the NS group. The NS group had statistically significantly higher cerebral artery atherosclerosis scores, especially in the anterior circulation. The NS group also showed higher T-CUS, although there were no significant differences compared with the control group. T-EUS in the NS group were higher than those in the control group. However, there were no differences in T-ABI scores between the two groups. The NS group demonstrated hypoalbuminemia and hypercholesterolemia, as well as anemia, increased creatinine level and low eGFR, which were consistent with chronic kidney disease. They also had high fibrinogen and D-dimer levels, indicating a hypercoagulable state (Table 3, 4).

Table 3. Comparison of clinical and atherosclerotic characteristics between patients with acute ischemic stroke and nephrotic syndrome due to diabetic nephropathy (NS group) and patients with acute ischemic stroke and diabetes mellitus without nephrotic syndrome (control group)

	NS group	Control group	P
Patient (n)	7	14	
Age, y	65.3 ± 9.3	66.0 ± 8.0	—
Sex/male	6 (85.7)	12 (85.7)	—
DM	7 (100)	14 (100)	—
Duration	12.3 ± 10.1	7.9 ± 6.2	0.397
Hb A1c	8.7 ± 3.3	8.1 ± 1.7	—
on medication	4 (57.1)	7 (50.0)	—
Hypertension	5 (71.4)	10 (71.4)	1
BMI	22.9 ± 2.4	22.9 ± 3.3	0.852
AIS LAA	5 (71.4)	3 (21.4)	0.056
SVO	2 (28.6)	11 (78.6)	
AS score	5.3 ± 3.7	2.1 ± 2.0	0.019
Anterior c	2.6 ± 1.8	0.9 ± 1.3	0.035
Posterior c	2.3 ± 2.9	1.1 ± 0.9	0.588
T-CUS	2.0 ± 2.3	0.6 ± 0.9	0.133
T-EUS	4.0 ± 1.0	1.8 ± 1.1	0.031
T-ABI	1.9 ± 0.4	2.1 ± 0.3	0.459

The differences between the two groups were evaluated statistically by χ^2 or Mann-Whitney's U tests.

Abbreviations: AIS – acute ischemic stroke; SVO – small-vessel occlusion; LAA – large-artery atherosclerosis; AS – atherosclerosis score; anterior c – anterior circulation; posterior c – posterior circulation; T-CUS – total carotid ultrasonic score; T-EUS – total extremities ultrasonic score; T-ABI – total ankle-brachial index.

Table 4. The comparison of laboratory data between the patients of acute ischemic stroke with nephrotic syndrome due to diabetic nephropathy (NS group) and acute ischemic stroke with diabetes mellitus without nephrotic syndrome (Control group)

	NS group	Control group	P
Albumin	2.7 ± 0.5	4.2 ± 0.4	<0.001
Total cholesterol	321.7 ± 42.5	211.7 ± 39.4	0.001
LDL-cholesterol	214.4 ± 40.5	132.6 ± 34.2	0.001
HDL-cholesterol	51.3 ± 17.4	49.4 ± 9.7	0.94
Triglyceride	229.0 ± 67.4	189.6 ± 203.1	0.037
Creatinin	2.1 ± 1.6	0.9 ± 0.3	0.009
eGFR	37.7 ± 23.3	71.5 ± 22.6	0.011
Hematocrit	35.7 ± 5.5	43.0 ± 5.1	0.006
Platelet	27.8 ± 2.7	22.4 ± 5.8	0.048
PT	0.9 ± 0.7	0.9 ± 0.0	0.55
APTT	28.9 ± 3.9	28.8 ± 3.1	0.933
Fibrinogen	385.4 ± 104.5	275.0 ± 57.9	0.019
D-dimer	1.8 ± 1.0	0.7 ± 0.4	0.01

The difference between two groups was statistically estimated by the method of χ^2 test or Mann-Whitney's U-test.

Abbreviations: LDL – low density lipoprotein; HDL – high density lipoprotein; eGFR – estimated glomerular filtration rate.

4. CEREBRAL VENOUS SINUS THROMBOSIS (CVT) ASSOCIATED WITH NS

1) CVT Patients (Table 5)

Case 1

The patient was a 46-year-old man. He had headache and vomiting the day after he drank heavily. Contrast brain computed tomography (CT) and MRI revealed a defect in the transverse sinus, straight sinus, and superior sagittal sinus. His blood was hemoconcentrated, and blood test results indicated high D-dimer and fibrinogen levels and decrease of antithrombin III.

Case 2

The patient was an 89-year-old woman. She suffered from ischemic colitis. She developed left hemiplegia and headache after having had diarrhea for a month. Brain CT revealed hematoma in the subcortical region of the right frontal lobe and a high signal in the straight sinus. The superior sagittal sinus showed high-signal intensity on T1-weighted MRI and mild high-signal intensity on T2-weighted MRI. High D-dimer and fibrinogen levels were detected in the blood.

We experienced 25 cases of CVT over a period of nine years from April 2004 to August 2013. Of these cases, two had a complication of NS. The incidence of NS in CVT patients

was 8.0%. Over the same period, we had 10 cases of AIS-associated NS, which is five times that of CVT associated with NS.

Table 5. The patients with cerebral venous sinus thrombosis

				MRI/CT							
Case	Age	Sex	Type	Location of occlusion	Alb	TC	UP	day	E	DM	NS type
1	46	M	CVT	SSS, LS, straight S	2.4	364	4	3.5	+	—	minimal change
2	89	F	CVT	SSS, straight S	1.9	326	4	>3.5	+++	—	unknown

Abbreviations: TC – total cholesterol; Alb – albumin; UP – urinary protein; E – edema; DM – diabetes mellitus; NS – nephrotic syndrome; CVT – cerebral venous sinus thrombosis; SSS – superior sagittal sinus; LS – lateral sinus (transverse sinus).

Table 6. The adult cases of cerebral sinus thrombosis with nephrotic syndrome

Abbreviations: Rx – treatment; MCD – minimum change disease; MCNS – minimum change nephritic syndrome; MPG – mesangial proliferative glomerulonephritis; MGN – membranous glomerulonephritis; CTIN – chronic tubulointestinal nephritis; AMD – amyloidosis; n.a. – not available; H – Headache; S – seizure; hemi-p – hemiplegia; SSS – superior sagittal sinus; LS – lateral sinus (transverse sinus); SS – sigmoid sinus; IJV – internal jugular vein; AC – anticoagulation therapy; lysis – endovascular thrombolysis; CR – complete remission.

2) Literature Review of CVT Patients with NS

We reviewed the literatures of CVT patients with NS since 1980. The 54 cases under 20 years old were reported from Japan (20 cases) and other countries (34 cases). The 29 adult cases over 20 years old, including our two cases, were reported from Japan (10 cases) and other countries (19 cases). Table 6 shows the clinical characteristics of 18 cases (12 male and 6 female), omitting those cases for which only an abstract was available [28-42]. The average age of the cases was 44.6 ± 18.5 years (20-89 years) and minimal change disorder was detected as the cause of NS in eight cases. The clinical symptoms included headache in 14 cases (77.8%), convulsion in five cases (27.8%), motor hemiparesis in seven cases (38.9%), cranial palsies in three cases (16.7%) and aphagia in two cases (11.1%). Occluded sinuses were observed in superior sagittal sinus or transverse sinus in 13 cases (72.2%).

NS had already been diagnosed in 13 cases before the occurrence of CVT, but in five cases was not diagnosed until the occurrence of CVT [29, 36, 39-41]. The patients showed the abnormal hypercoagulation, including decreases of antithrombin III in six cases, decrease of protein S in two cases, increased fibrinogen in 10 cases, positive lupus anticoagulant in three cases, positive antinuclear antibody in two cases, factor V Leiden mutation with hyperhomocysteinemia in one case, hemoconcentration in two cases, hormone replacement therapy with estrogen in one case, preeclampsia in one case, SLE in one case, rheumatoid arthritis (RA) in one case, ischemic colitis with diarrhea in one case, and heavy drinking in one case (Table 7).

5. INTRACEREBRAL HEMORRHAGE (ICH) ASSOCIATED WITH NS

1) ICH Patients

Case 1

A 51-year-old woman was admitted to our hospital with headache and vomiting. She had right hemiparesis and speech disturbance. At age 46, she had suffered from DM, but did not take any medications. At age 47, she had double vision due to right abducent nerve palsy, and was diagnosed as having a right carotid-cavernous fistula (CCF). Endovascular coiling embolization was performed. On admission, she had slight unconsciousness (JCS I-2), dysarthria, and right side hemiparesis. NIHSS was 5 points. Her blood pressure was 170/92 mmHg. MRI showed the subcortical hemorrhage (7.1 ml) in the left temporal lobe. No abnormal vessel or microbleeds were detected in MRA and T2* weighted MRI. The conservative treatment was performed, but the peripheral edema and pleural effusion were not improved. On day 12, she was transferred to a specialist nephrology hospital, scoring 3 on the modified Rankin scale (mRS).

Case 2

A 63-year-old woman was admitted to our hospital because of gait disturbance. She had left hemiparesis and speech disturbance. At age 56, she had suffered from intracerebral hemorrhage (left putamen), and was under the treatment of hypertension and DM for several

years. On admission, she had slight unconsciousness (JCS I-2), dysarthria, and left side hemiparesis. She also had slight residual of right hemiparesis. Bilateral pyramidal tract signs were observed. NIHSS was 6 points and her blood pressure 220/120 mmHg. A peripheral edema was observed in her lower extremities. MRI showed a hemorrhage (2.2 ml) in the right putamen, and an old lesion (slit) in the left putamen. No microbleeds were detected in T2* weighted MRI. On day 16, the patient was transferred to a rehabilitation hospital on mRS 2 following treatment on the acute stage of putaminal hemorrhage.

Case 3

A 72-year-old man was admitted to our hospital because of generalized convulsion. He had recurrent episodes of lobar hemorrhage (subcortical hemorrhage). He was bed-ridden after 10 episodes over a period of several years. He had vascular dementia (MMSE; 7/30 points). On admission, he had quadriplegia and bulbar palsy, showing bilateral pyramidal signs. He showed dyspnea due to pneumonia and marked peripheral edema in his extremities. His blood pressure was 104/70 mmHg. He had no DM. MRI showed a subcortical hemorrhage in right frontal lobe, and many microbleeds in bilateral frontal, temporal, parietal and occipital lobes, some of which presented as accumulations or clusters. MRA showed multiple stenosis of intracerebral arteries. The patient was diagnosed with cerebral amyloid angiopathy. He was treated by methyl prednisolone, but the excretion of urinary protein was not improved. Two months later, he was transferred to a specialist nephrology hospital on mRS 5.

Case 4

A 76-year-old man was admitted to our hospital because of vertigo. At age 52, he had a subarachnoidal hemorrhage and underwent an operation for a ruptured aneurysm. For several years, he received treatment for hypertension and DM, which were not well controlled. On admission, he had cerebellar ataxia and dysarthria, but no meningeal irritation or pyramidal signs. NIHSS was 3 points. His blood pressure was 200/80 mmHg. He showed peripheral edema in his lower extremities. MRI showed the hemorrhage (3.1 ml) in the deep part of left cerebellar hemisphere with little extravasation in ventricles. An old infarct lesion in the right temporal lobe and ventricular dilatation were recognized. On day 26, he was transferred to a rehabilitation hospital on mRS 5 after treatment on the acute stage of the cerebellar hemorrhage.

Tables 8 and 9 show the clinical characteristics of, and laboratory findings for the patients with ICH with NS. Increases of HbA1c, fibrinogen, d-dimer and creatinine were found in three cases, two cases, two cases and three cases, respectively. Serum level of antithrombin III was normal in two cases examined. ABI was abnormal in one case, and ultrasonography of carotid artery detected mild to moderate stenosis of internal carotid artery in two cases.

The basic diseases underlying NS were suggested as amyloid nephropathy in Case 3 and DMN in Cases 1, 2 and 4. The incidence of ICH associated with NS was 0.18% of total stroke or 0.036% of ICH.

Table 7. The hypercoagulability factors in the cases of cerebral sinus thrombosis with nephrotic syndrome

Cases	Age/sex	D-dimer‡	AT III	Procin S	Fbg	LA	ANA	others

Abbreviations: Cr – creatinine; eGFR – estimated glomerular filtration rate; DM – diabetes mellitus; year – years of disease duration; TG: triglyceride – HDL – high density lipoprotein; LDL – low density lipoprotein; Hct – hematocrit; Plt – platelet counts; PT – prothrombin time; aPTT – activated partial thromboplastin time; Fbg – fibrinogen; AT – antithrombin.

Figure 3. CT and MRI of the patients with intracerebral hemorrhage Case 1 (A, B); The arrows indicated subcortical hemorrhage (7.1 ml) in the left temporal lobe. The broad arrow was the artifact due to the coils. A, Brain CT, B; T1 weighted image, 1.5T, axial, TR; 525ms, TE; 12 ms . Case 2 (C, D); The arrows indicated the hemorrhage (2.2 ml) in the right putamen, and the broad arrow indicated the old hemorrhagic lesion of the left putamen. C, Brain CT, D; T2* weighted image, 1.5T, axial, TR; 660 ms, TE; 25 ms. Case 3 (E, F); Broad arrow indicated subcortical hemorrhage in the right frontal lobe. Many micro bleeds were showed, and some (arrows) were clustered. Brain atrophy with ventricular dilatation and periventricular high signals were also elucidated. E; T2* weighted image, 1.5T, axial, TR; 814 ms, TE; 24.6 ms. F; T2 weighted image, 1.5T, axial, TR; 10000 ms, TE; 120 ms. Case 4 (G, H); The hemorrhage (arrow) in the deep part of cerebellar hemisphere, the old infarct (broad arrow) in the polar head of right temporal lobe and the ventricular dilatation (arrow heads) were shown. G; Brain CT, H; T1 weighted image, 1.5T, axial, TR; 530 ms, TE; 12 ms.

DISCUSSION

Patients with NS have a high incidence (21 to 51% of patients) of venous thrombosis, particularly deep vein and renal vein thrombosis, and pulmonary emboli, especially in younger patients under 20 [43-48], and CVT has also (rarely) been reported [2]. On the other hand, the relative risk of arterial thrombosis is low (1.0 to 5.5%), compared to that of venous thrombosis [3, 49, 50]. In 2014, Sasaki et al. reported an additional case of AIS with NS, and reviewed 21 prior cases reported in 19 literatures [4]. However, the incidence and clinical characteristics of AIS patients have remained unclear [5-10]. We reported six LAA patients, three SVO patients and one CE patient, and elucidated the following. The incidence of AIS associated with NS was 0.09% of total stroke or 0.12% of AIS, and five times that of CVT in the adult patients with NS. The patients had severe stenosis and/or occlusion of intracranial cerebral arteries, especially in the cerebral anterior circulation, and also demonstrated atherosclerosis of the internal carotid and lower extremity arteries. The patients had high serum fibrinogen and D-dimer levels, suggesting that AIS patients with NS have a greater degree of hypercoagulability than AIS patients without NS. The pathogenesis of NS was from DMN in eight cases (80%), amyloid nephropathy in one case, and MPGN in one case. These results suggest that the AIS patients with NS, especially from DMN, had marked general arteriosclerosis of the body, which might be a clinical characteristic peculiar to Japanese patients [24].

Mahmoodi et al. reported that annual incidences of venous and arterial thromboembolism in NS patients were 1.02% and 1.48%, respectively – eight times higher than in general population from a retrospective cohort study. They also reported that multiple classic risk factors for atherosclerosis are associated with arterial thromboembolism in NS patients, including sex, age, hypertension, DM, smoking, prior arterial thromboembolism, and eGFR. The annual incidence of DMN patients was 7.43, which was the highest incidence among all types of nephropathy [3].

Sasaki et al. reported that histopathology of NS in the 22 AIS patients previously reported from several countries was membranous nephropathy in five cases (22.7%), minimal change in four cases (18.2%), MPGN in three cases (13.6%), focal segmental sclerosis in two cases (9.0%), Ig A nephropathy, undetermined pathology in six cases (27.2%), and DMN in only one case (4.5%) [4]. In our study, DMN was clinically apparent for the pathogenesis of NS in 80% of patients. The occurrence of non-diabetic renal disease (NDRD) in DMN patients has been increasingly recognized in recent years. Zhuo et al. reviewed the 13 literatures from the period between 1983 and 2012, and reported the prevalence of DMN complicating NDRD; the common histological diagnoses were tubule-interstitial nephritis (22.7%) and IgA nephropathy (14.1%) [51]. The complication of NDRD notwithstanding, DMN could be the primary cause of the pathogenesis of NS in 80% of our patients. The patients with NS had the combined risks from the basic, disease-induced NS, as well as the hypercoagulation state arising as a result of NS. It is well known that DM and hyperlipidemia are strong risk factors for AIS, but it is possible that the existence of NS may be another risk factor. DM may be the strongest and most important risk factor for AIS associated with NS, especially in Japanese patients.

CVT commonly occurs in young adults under 40 years old, and is around three times more common in females than in males. Its incidence is about 0.5-1.0% among all types of

stroke. There are many risk factors of CVT, one of which is NS [2, 11, 12, 52-54]. Twenty-five patients (aged 59.8 ± 18.6 years; 20 men and five women) were admitted to our center during a nine-year period between April 2004 and August 2013 [55]. The incidence of CVT in our study was 0.22% of all kinds of strokes or 0.30% of ischemic infarctions, which may be lower than previously reported. The patients with CVT in our study had, as risk factors, oral contraceptive use (two patients), deficiency of protein S (three patients) and antithrombin (two patients), nephrotic syndrome (two patients), iron deficiency anemia (three patients), colon cancer (one patient), and multiple myeloma in remission (one patient). Furthermore, hyperhomocysteinemia was identified in nine (56.3%) of 16 patients tested (Table 10). Our results show that the CVT patients in Japan may be older and include fewer females than CVT patients in Western countries [55]. The most common risk factor in women has been reported to be oral contraceptive use [2, 11, 12, 14, 15, 16]. Oral contraceptive use has been reported to be less prevalent as a cause of CVT in Japan than in Western countries [56]. This may be due to few young female CVT patients using oral contraceptives in Japan.

NS is one of the risk factors for CVT [28, 53, 54]. A multinational (21 countries), multicenter (89 centers) prospective observational study entitled 'The International Study on Cerebral Vein and Dural Sinus Thrombosis' (ISCVT) [52, 57-60] examined 624 cases of CVT. ISCVT and other studies reported that the prevalence of NS was 0.6-2% [12, 52, 54, 61]. In our study, NS was recognized as a risk factor for CVT in two out of 25 cases (8.0%) [55]. Our study was not performed in multiple centers, but in only one center. In the future, a nationwide prospective study needs to be performed in order to clarify the characteristics of CVT in more detail, especially its risk factors, in Japanese patients of all ages. Patients with NS have a thrombotic tendency; both venous thrombosis and arterial thrombosis may occur. In the literature, the number of published cases of CVT was tenfold that of cerebral artery thrombosis as a complication of NS in individuals aged <20 years. In adults, however, the number of cases of CVT reported was twice that of cerebral artery thrombosis cases. Venous thrombosis is likely to occur in young cases with NS, and both venous and arterial thromboses are likely to occur in adult cases [25]. NS shows a thrombotic tendency, but the onset of CVT may develop as a result of some additional thrombotic factor, such as hemoconcentration after heavy drinking, diarrhea, or vomiting. Lifestyle management alongside the conventional treatment of NS is important.

It is well known that hemorrhagic lesions possibly occur as an associated complication of CVT [2]. However, the clinical details of ICH-associated NS have not been reported [62]. Patients with NS have a thrombotic tendency, which, as described above, is a risk factor for both venous thrombosis and arterial thrombosis. When we retrospectively analyzed the hospitalized patients, however, we not only found the 10 AIS and 2 CVT patients with NS, but also, unexpectedly, four ICH patients with NS [26]. The incidence of ICH associated with NS was 0.18% of total stroke or 0.036% of ICH. The basic disorders associated with NS were DMN and amyloidosis in three cases and one case, respectively. These patients had strong risk factors for ICH, such as hypertension, vascular vulnerability with atherosclerosis or amyloidosis, with change of bloodstream after operation, suggesting that they had overcome the risk of thrombophilia (Figure 3). NS essentially associates with a risk for venous or arterial thrombosis. Attention should also be paid to NS as a risk factor for ICH.

The main cause of NS in children is minimal change disease (MCD). On the other hand, approximately 30% of adults with NS have a systemic disease, such as DM, amyloidosis, or SLE. The remaining cases are usually due to primary disorders including MCD, focal

segmental glomerulosclerosis (FSGS), and membranous nephropathy. The frequency of the different forms of nephropathy underlying NS in adults was evaluated in renal biopsy registries of several counties [63-70]. Among patients between the ages of 15 and 65, the most common causes of NS were membranous nephropathy, MCD, lupus nephritis, FSGS, MPGN, amyloidosis, and IgA nephropathy. A similar distribution was observed among elderly individuals (aged above 65 years), except for an increased prevalence of amyloidosis and a decreased prevalence of lupus. The frequency of the DMN in these registries was ~1-5% [63-70].

Table 10. The risk factors and etiology in the patients with cerebral venous sinus thrombosis

Patients	n = 25	%
Sex (male)	20	80
Age		
Male	59.8 ± 17.6	
Female	59.6 ± 24.4	
Lab. findings and risk factors		
d-dimer n = 20	20	100
Protein C deficiency n = 15	0	0
Protein S deficiency n = 15	3	20
Antithrombin deficiency n = 14	2	14.3
ANA n = 14	0	0
Anti-phospholipid syndrome n = 15	0	0
CRP n = 21	19	90.5
Fibrinogen n = 18	14	77.8
Anemia (fe def.) n = 25	3	12
Homocysteine n = 16	9	56.3
Oral contraceptives (female n = 5)	2	8 (40)
Nephrotic syndrome	2	8
Malignancy	1	4
Others (associated)		
Multiple myeloma	1	
Multiple sclerosis	1	
Neurofibromatosis 1	1	
Epilepsy	1	

In Japan, the frequency of nephropathy underlying NS was pathologically evaluated in the Japan Renal Biopsy Registry (J-RBR) of 2,751 patients. Among patients between 20 and 65 years of age, the most common causes of NS were membranous nephropathy (18%), minimal change disease (25%), DMN (12%), lupus nephritis (10%), FSGS (7%), MPGN (2%), amyloidosis (2%), and IgA nephropathy (7%). Among the elderly individuals (age greater than 65 years), the most common causes of NS were membranous nephropathy (32%), MCD (13%), DMN (10%), lupus nephritis (2%), FSGS (6%), MPGN (4%), amyloidosis (8%), and IgA nephropathy (4%). The most remarkable characteristic form underlying NS in the J-RBR evaluation was the higher frequency of DMN than those in the other registries [71,

72]. Furthermore, it has recently been reported that 41.4% of 614 patients with pathologically confirmed DMN registered in J-RBR were in a clinically nephrotic state [73]. In our stroke registry, DMN was the main disorder underlying NS in both AIS and ICH associated with NS (Figure 4). Long-term DM could damage the arterial vessels so as to precipitate the occurrence of both diseases. On the other hand, DM cannot significantly damage the veins, indicating that the thrombotic tendency due to NS may be the main player in causing CVT. NS tends to be associated with a risk factor for AIS and CVT, and attention must also be paid to ICH associated with NS in cases of stroke.

CCF: carotid-cavernous fistula.

Figure 4. The factors of thrombotic tendency and the factors of bleeding tendency in the patients with intracerebral hemorrhage associated with nephrotic syndrome.

AIS		CVT		ICH	
NS	0.12 %	8.0 %		0.036%	
n=10		n=2		n=4	
DMN 8		MCD 1		DMN 3	
AMD 1		nd 1		AMD 1	
MPGN 1					

AMD – amyloido nephropathy; MPGN – membranoproliferative glomerulonephritis; MCD – minimal change disease.

Figure 5. Nephrotic syndrome (NS) and diabetic nephropathy (DMN) in the patients with acute ischemic stroke (AIS), cerebral venous sinus thrombosis (CVT) and intracerebral hemorrhage (ICH).

Chapter 90

POST-STROKE DYSPHAGIA

Massimiliano Toscano*, MD, PhD and Vittorio Di Piero, MD, PhD

Department of Neurology and Psychiatry – Stroke Unit, “Sapienza” University of Rome,
Rome, Italy

ABSTRACT

Dysphagia is a common consequence after stroke, presenting in up to 50% of all acute stroke patients, with increased morbidity and mortality mainly because it dramatically increases the risk of aspiration pneumonia, and because it leads to malnutrition and dehydration as well.

It has been reported that the incidence of dysphagia ranges from 25% to 81% depending on the timing of the assessment, diagnostic methods and criteria.

The nervous system affected by a stroke damage is thought to reserve a variable ability to somehow reorganize damaged pathways and structures, allowing an effective recovery from swallowing impairment.

Notwithstanding, about half of stroke patients remain dysphagic after seven days from symptoms onset, and approximately 13-15% of patients has persistent swallowing dysfunction after six months, with a dramatic impact on patients' outcome in terms of increased likelihood of residential placement and estimated lifetime costs in stroke survivor.

To date, it is unclear why some stroke patients develop a persistent swallowing impairment after stroke or, in other words, if the failure in recovery from dysphagia is due to a stroke involving the dominant swallowing hemisphere, rather than a swallowing key region, or even to any specific clinical or neuroradiological stroke factor.

In this view, stroke severity upon admission, assessed using NIHSS, is an important clinical predictor of post-stroke dysphagia and of a persistent pattern of dysphagia as well.

Regarding the site of the stroke lesion, it is widely accepted that swallowing function is provided by a complex neural network bilaterally involving the perirolandic sensorimotor cortex which, together with other cortical structures, projects and receives

* Corresponding author: Massimiliano Toscano, MD, PhD. Department of Neurology and Psychiatry, “Sapienza” University of Rome, Viale dell’Università 30, 00185 Rome. Phone: +39 06 49914682, fax: +39 06 49694254, e-mail: massimiliano.toscano@uniroma1.it.

afferences to the brainstem' Central Pattern Generator, through the basal ganglia, the thalamus and the periventricular white matter as well. Despite several cortical areas have been described as related with swallowing impairment, a definite role in causing dysphagia has been not completely understood for all of them so far.

Interestingly, recent studies reported that the disruption of cortical-cortical and cortical-subcortical white matter connections seems to increase the risk of dysphagia and aspiration pneumonia by lowering the threshold of input to the medullary swallowing center.

Thus, dysphagia may result from the combined effects of an acute focal damage and a preexisting impairment of the subcortical white matter connecting pathways. In other words, we might think of dysphagia as a kind of deficit in executive functions, which we know to be particularly associated with leukoaraiosis and cognitive disorders, and of course age.

Keywords: leukoaraiosis, dysphagia, stroke

INTRODUCTION

Dysphagia is a common consequence after stroke, presenting in up to 50% of all acute stroke patients. It has been reported that the incidence of dysphagia ranges from 25% to 81% depending on the timing of the assessment, diagnostic methods and criteria.

The clinical and scientific relevance of post-stroke dysphagia is demonstrated by its high incidence and negative effect on clinical outcome, with increased morbidity and mortality mainly because it dramatically increases the risk of aspiration and pneumonia [1, 3-6].

In this view, pulmonary infections represent one of the most common and fearsome complications in stroke patients: SPREAD guidelines report that, along with urinary infections, it reaches a cumulative incidence of about 30%, hence far exceeding that of other internal medicine complications [7].

Aspiration pneumonia is also associated with a relevant worsening of stroke outcome: a recent multicenter observational study, carried out on 8,250 stroke patients, confirmed that lung infections in patients with stroke are associated with worsening of mortality both at 30 days and at one year after the acute phase of stroke, with an increased length of stay, a greater disability at discharge, and an increased percentage of stroke patients sent in long-term care [4].

In the literature there are also conflicting reports on the consequences of the so called "silent aspiration," which is the aspiration of swallowed material without any clinical manifestations, and thereby underdiagnosed. It is estimated to be prevalent in 15-39% of patients with subacute stroke and in 2-25% of unselected patients with acute stroke, with a relevant increase in relative risk of pneumonia and a poorer clinical outcomes for silently aspirating patients compared with overt/non-aspirators [8, 9].

This data, as well as the strong evidence that dysphagia significantly contributes to malnutrition and dehydration regardless of aspiration [10], highlight the dysphagia's dramatic impact on patients outcome, with increased likelihood of residential placement and significantly increases estimated lifetime costs in stroke survivors [11].

NEURAL CONTROL OF SWALLOWING

It is now widely recognized that swallowing process is mediated by neural pathways that involve cortical input reaching the brainstem by means of fibers, such as the corticobulbar tract, which connect cortical areas that control swallowing with bulbar nuclei that mediate the final mechanism; however, the role of the different cortical and subcortical areas in causing dysphagia is still not entirely clear.

Several studies have dealt with identifying those structures involved in the process of swallowing.

In the past, researchers have mainly focused their attention on specific regions of the brainstem, in order to evaluate the action of interneurons involved into the oral and pharyngeal swallowing.

The focus then shifted on the observation of the interaction between different cortical areas and brainstem nuclei to control swallowing [12-15].

At a subcortical level, a consistent peristaltic contraction is guaranteed by a number of interneurons located in the reticular formation, in the nucleus of the solitary tract and in the nucleus ambiguus as well, all regions which constitute the swallowing core regulator of the brainstem. These centers are responsible for the integration of information coming from the oropharynx, esophagus and from supranuclear structures and are classically described as “central pattern generator” (CPG).

CPG is mainly entrusted with the control of both timing and synchronism of swallowing process. In any case, the brainstem is a part of a complex cortical-subcortical network which involves a sensory system, motor system, and white matter pathways. In this point of view, the majority of the recent studies highlight that the integrity of these connections appears to be fundamental for an effective coordination of swallowing to be achieved [16-18].

Brainstem and Peripheral Control

Since early researches carried on by Car and coworkers [19, 20], the brainstem has been described as responsible for the complex sequences and execution of the neuromuscular events involved in swallowing, by means of the compact clustering of bilateral cranial nerves nuclei and interneuronal connections as well [21]. The very first evidence of this role came from a study of decerebrated animals [22]: it has been demonstrated an elicitation of pharyngeal and esophageal swallowing obtained by stimulating this area in the absence of cortical input.

It is now widely accepted that brainstem structures provide the basic motor plan for pharyngeal swallowing, being also involved in the coordinative interactions between swallowing and respiration [23].

As mentioned above, the swallowing core regulator of the brainstem is represented by the Central Pattern Generator (CPG), a structure located into the rostral and ventrolateral portion of the brainstem. From an anatomical and functional point of view, the CPG has been classically divided in two bilateral region [24]: a dorsal region, which includes the nucleus of the solitary tract (NTS) with the adjacent reticular formation, and a ventral region, represented by the area surrounding and including the nucleus ambiguus (NA).

Since NTS represents the primary sensory nucleus for the VII, IX and X cranial nerve, the dorsal region is thought to represent the initial neuronal entrance for input that modulates swallowing: sensitive afferent fibers originate from mucosal chemoreceptors, mechanoreceptors and thermoreceptors of the oral cavity, pharynx and larynx; these fibers are involved in both the initiation and repeated activation of pharyngeal phase of swallowing, and are essential for the protection of the airway by the phenomenon of aspiration.

Muscle spindle receptors located in the pharyngeal and esophageal swallowing muscle, are otherwise considered as a trigger for those interneurons that modify motor output to muscle [21].

Otherwise, CPR ventral region is involved in sending out neural commands that control pharyngeal, laryngeal, and esophageal muscles. This motor task is carried out by means of NA, which is the primary motor nucleus for IX, X and XI cranial nerves, and has several interconnections with other medullary motor nuclei, such as those of V, VII and XII cranial nerves.

NA also contains axons projected to contralateral brainstem regions, suggesting that the ventral region has also a role in the integration of sensory information; this suggestion is otherwise confirmed by the fact that the ventral efferent medullary region receives direct input from the dorsal afferent medullary one. Hence, it could be argued that sensory information entering the brainstem via the NTS is integrated by the NA into a swallowing motor plan, and then transmitted to the motor nucleus for execution [21].

Finally, the interneuronal networks localized in CPG integrates sensory information by modulating afferent and efferent pathways activation which reciprocally connects the brainstem to the higher centers. This circuit is thought to represent the way how motor circuits are modulated by sensory feedback pathways, depending on bolus characteristics, head position and on muscular activity.

Higher Nervous System Control

While the basic motor plan for pharyngeal swallowing is provided by brainstem structures, the start of swallowing is a voluntary act which depends on the integrity of several cortical areas.

It has been suggested that the programming of the swallowing process firstly occurs in non-primary motor areas (i.e., mesial premotor cortex), secondly involving the primary sensorimotor cortex, and finally reaching the secondary areas.

Several studies [25-29] have identified numerous areas of interest who have a significant role in swallowing, such as the premotor cortex, the primary sensorimotor cortex, the insula, as well as some limbic areas. However, although these foci have been consistently identified in many of these studies, the exact width and functional relevance of the entire swallowing network have not been entirely clarified so far.

Discrepancies between the studies probably reflect methodological differences: the main imaging techniques used to investigate the neural basis of swallowing (i.e., functional Magnetic Resonance Imaging (fMRI), Positron Emission Tomography (PET) and Magnetoencephalography (MEG)) actually offer a representation of different aspects of brain activity. FMRI detects changes in local cerebral oxygenation, closely linked to the underlying neuronal activity; PET uses radioactive markers to study local changes in neurophysiological

parameters as cerebral perfusion and glucose consumption; finally MEG measure small magnetic fields arising from neural.

Among these, fMRI is the most widely adopted technique, mainly because of its safety and its spatial resolution of about 4 mm; hence according to some Authors it could be used as an auxiliary technique to the conventional MRI to investigate the dysphagia following brain injuries. However even fMRI studies are heterogeneous with regard to the task investigated (voluntary or reflex swallowing, number of swallows, etc.).

An interesting meta-analysis [30] based on the activation likelihood estimation (ALE), has compared some of these studies in order to better identify brain areas involved in both water and saliva voluntary swallowing. The ALE is a quantitative voxel-wise meta-analysis technique which estimates the probability of brain activation in a given voxel, by analyzing the results of several studies expressed as standard space coordinates of activation maxima. The meta-analysis of brain activation showed that the significant activation clusters seen during water swallowing were partly different from those seen during saliva swallow. Authors also performed a between condition meta-analysis showing that, despite a partial overlap in the network involved in water and saliva swallowing, the first is strongly associated with right inferior parietal activation, while the latter more strongly involves premotor areas. This datum suggests that water swallowing strongly activates those cortical areas involved in sensory processing of intraoral water stimulation, while saliva swallowing massively involves premotor areas, which are crucial for initiation and control of swallowing sequence movements.

To have an overview of the several cortical and subcortical regions involved in swallowing, Table 1 report those dysphagia regions of interest, as identified by a recent meta-analysis [31], describing both those areas for which there is a clear implication, identified by most studies, both those ones whose role is still under discussion. The hypothesized role in swallowing mechanisms is labelled as well.

Table 1. Cortical and subcortical regions involved in swallowing

Region of Interest (ROI) Selected For Analysis and Hypothesized Role in Swallowing		
ROI	Role	References
Primary Somatosensory, Motor and Motor Supplementary cortices (BA 1, 2, 3, 4, and 6)	Cortical processing of swallowing, including motor regulation and execution and sensorimotor control	Hamdy et al., Martin et al., Mosier and Bereznaya

Initial studies in healthy volunteers described the midline swallowing muscles as bilaterally represented in the motor cortex, but in an asymmetric manner [12]. The Authors highlighted that in the majority of subjects, pharyngeal and esophageal projections from one hemisphere tended to be larger than those from the other one, suggesting a bilateral but asymmetric motor representation for swallowing musculature between the two hemispheres independently from handedness.

Using a complex paradigm, Hamdy et al. conducted a functional study of the cerebral loci that processes the human volitional swallowing with Positron Emission Tomography (PET) activation imaging, coupled in the same subjects with the single-pulse TMS with EMG recording in order to map the cortical motor representation of pharynx [32]. They firstly confirmed that the normal cortical representation of swallowing is bilateral and asymmetrical; moreover, the findings of sensorimotor cortex lateralization with PET were concordant with the cortical motor representation findings from TMS mapping, suggesting that also the motor aspects of swallowing show some degree of cortical asymmetry.

Lateralized cortical systems has also been indirectly investigate with the dual-task paradigm, by comparing the performances obtained at “baseline” with those obtained while performing specific tasks such as the finger-tapping, the line orientation and the repetition silent [33]. Swallowing was measured at baseline and during each of the three tasks to identify the different contribution of each hemisphere. Swallowing resulted to be impaired by concurrently performing the silent repetition, which mainly activates the left hemisphere, along with the line orientation, a visuospatial process that mostly activates the right hemisphere. Both the finger tapping of the right hand and that of the left hand, that selectively activate their contralateral sensorimotor cortex, interfere with swallowing. Moreover the

silent repetition leads to a significant change in the volume of the bolus, while the line orientation seems to have a negative impact on the number of swallows.

Even though it is now widely accepted the existence of a dominant hemisphere for swallowing in each individual, which is however independent from being left or right-handed, it has been not identified a hemisphere uniquely related to dysphagia so far; Notwithstanding, it has been suggested an association between the left hemisphere and the coordination of the oral voluntary phase, and between the right hemisphere and the pharyngeal automatic phase. In this light, evidences from literature suggest that there is an increased tendency for the pharynx to be involved, whether the damage is limited to the right hemisphere [34]; it is also intriguing that some Authors also described an asymmetrical cerebellar activation during swallowing, with a strong lateralization to the left cerebellar hemisphere and/or vermis; this seems to confirm the aforementioned hypothesis that the left brain is mostly involved in the coordination of the oral voluntary phase, while the right hemisphere seems to give a more relevant contribute to the pharyngeal automatic phase.

LESION LOCATION

From a historical point of view, for many years it was thought that a stroke must involve the brainstem or both hemispheres in order to cause dysphagia.

Since many studies over the last three decades have highlighted that also a single unilateral stroke is able to cause a swallowing impairment [34], many efforts have been made to identify those cortical and subcortical region whose damage could affect swallow mechanisms.

The importance of CPG in swallowing control is confirmed by the high incidence of dysphagia in patients with Wallenberg syndrome or lateral bulbar syndrome. Ischemia occurring at this level affects the nucleus of the solitary tract, the nucleus ambiguus and nuclei of the cranial nerves involved in swallowing. The impairment of the nucleus of the solitary tract can affect both the start and the synergy of the pharyngeal phase of swallowing; moreover, dysphagic patients with lesions at this level, have a hypoactivation of those brainstem areas resulting in a swallow impairment which mostly concerns the pharyngeal phase. Otherwise, the damage of the nucleus ambiguus leads to paralysis of the ipsilateral pharyngeal muscles, laryngeal and soft palate.

Flowers et al. [26] highlighted that other brainstem areas, such as the midbrain, the pons, and the lateral and medial portions of the bulb, are strongly correlated with post-stroke dysphagia. They reported as associated with dysphagia midbrain lesions in 6% of cases, pontine lesions in 45%, injuries in the medial bulb in 40%, and in the lateral bulb in 57% of cases; hence there would be a greater risk of swallowing dysfunction after pontine and bulbar stroke.

Also stroke involving insula seems to have a pivotal role in causing dysphagia, since lesions occurring at this level seem to be related to buccofacial apraxia and to a pharyngeal dysphagia strongly associated with aspiration [35].

Daniels and colleagues [27] also claimed that stroke lesions involving the insula may cause dysphagia by means of the disruption of the cortical-subcortical pathway which connect the anterior insula, both the primary and the supplementary motor cortex, the ventroposterior

medial nucleus of the thalamus and the nucleus of the solitary tract as well, all structures entrusted in the integrated mechanisms of oropharyngeal swallowing.

It was also observed that basal ganglia, and the associated neural pathways as well, play a role in the pathogenesis of post-stroke dysphagia by means of the progressive involvement of excitatory and inhibitory corticobulbar fibres. In this view, basal ganglia functionally connect the cerebral cortex and thalamus by providing a gate for sensory input entrusted in the motor control of the swallowing. Hence lesions of the basal ganglia and internal capsule are primarily associated with disorders of oral movement control, due to a premature leak of the bolus into the valleculae or the pyriform sinuses [12].

Since the last years, at a subcortical level, it has been a growing attention for the periventricular white matter [36]: the anterolateral portion of periventricular white matter contain both corticospinal descending motor fibers for the mouth and face, and ascending somatosensory ones as well. These ascending and descending fibers are embedded in an intrahemispheric cortico-cortical pathways: they cross the descending corticospinal fibers from the mouth/face representation within the ventrolateral precentral gyrus (motor cortex), and interconnect with specific cortical, subcortical, and brainstem regions involved in swallowing.

To date the role of cerebral small vessel disease (i.e., lacunar infarcts and white matter hyperintensities) in acute post-stroke dysphagia is still unclear. Notwithstanding it has been suggested that disruption of cortical-cortical and cortical-subcortical white matter connections may increase the risk of dysphagia and aspiration by lowering the threshold of input to the medullary swallowing center.

As far as it concerns cortical lesions, it is reported that a stroke that damages the contralateral precentral gyrus can produce deficits in motor control of the face, lips and tongue and compromise the pharyngeal peristalsis. This type of injury also cause deficits in attention and concentration, hence leading to alterations in the control of the swallowing.

Otherwise, despite several cortical areas have been described as related with swallowing impairment, a definite role in causing dysphagia has been not completely understood for all of them so far. Table 2 shows dysphagia regions of interest as identified by a recent meta-analysis [29]; Authors reported both those areas for which there is a clear implication, identified by most studies, both those ones whose role is still under discussion.

In conclusion, these evidences from the literature suggest that swallowing function is provided by a complex neural network bilaterally involving the perirolandic sensorimotor cortex which, together with other cortical structures, projects and receives afferences to the brainstem' Central Pattern Generator, through the basal ganglia, the thalamus and the periventricular white matter as well.

CPG provides in turn the basic motor plan for pharyngeal swallowing, and coordinative interactions between swallowing and respiration as well [22], by means of its compact clustering of bilateral cranial nerves nuclei and interneuronal network; through this network, sensory information entering the brainstem from the peripheral structures is integrated into a swallowing motor plan, and then transmitted to the motor nucleus for execution.

Finally, it is worthy of note that, despite the large number of studies, what cortical and subcortical areas are clearly related to dysphagia are not fully clarified so far, nor is it clear how and where their input are integrated and elaborated in order to create a voluntary and functional control of swallowing.

Table 2. Cortical regions involved in swallowing

Region of Interest (ROI) Selected for Analysis and Hypothesized Role in Swallowing		
ROI	Role	References
Primary Somatosensory, Primary and Supplementary Motor cortices (BA 1, 2, 3, 4, and 6)	Cortical processing of swallowing, including motor regulation and execution and sensorimotor control	Hamdy et al., Martin et al., Mosier and Bereznaya
Anterior cingulate (BA 24 and 32)	Higher order motor processing: swallowing movement planning and execution	Hamdy et al.
	Cognitive perceptual processes (attention and response selection)	Martin et al.
Orbitofrontal cortex (BA 10, 11, 12, 44, 45, 47)	Unclear	Mosier et al.
Parieto-Occipital cortex (BA 7,17, 18, 40)	Sensory processing of swallowing	Hadmi et al., Kern et al.
	Task-cue processing (not swallowing per se)	Toogood et al.
	Movement planning and execution	Mosier and Bereznaya
Temporopolar cortex (BA 22 e 38)	Unclear	Mosier et al.
Insular Cortex	Processing of gustatory input	Daniels et al., Daniels and Foundas
	Intraoral sensory modulation	Mosier et al.

DIAGNOSTIC ISSUES

As mentioned above, there is a great variability among reported post-stroke dysphagia incidence between studies, thereby resulting in a conflicting data concerning dysphagia risk factor, swallowing impairment recovery, and its clinical and neuroanatomical correlate as well.

This wide range of variability is mainly due to both diagnostic criteria and assessment methods issues.

With regard to the criteria used for post-stroke dysphagia diagnosis to be made, it is worth considering what exactly is meant by the term dysphagia: oropharyngeal dysphagia is probably best defined as a disruption of bolus flow through the mouth and pharynx, as resulting from multiple measures of bolus flow, structural movement and patient perception as well [37].

Several studies aimed to investigate post-stroke dysphagia actually referred to aspiration, a related but distinct term which means the penetration of food material into the airways and below the true vocal cords.

From this point of view this seems somehow misleading, firstly because it is well known that dysphagia may occurs without aspiration; moreover, even with an instrumental evaluation, the incidence of dysphagia may be overestimated if its identification is based on

laryngeal penetration or single occurrences of aspiration [28], as also healthy subjects may exhibit laryngeal penetration and sometimes aspiration as well [20].

Finally, by focusing on the overt sign of aspiration to diagnose post-stroke dysphagia, such as cough or voice change, the aforementioned silent aspiration would be missed, with a relevant increase in relative risk of pneumonia and a poorer clinical outcomes.

Concerning the implied diagnostic methods, the post-stroke dysphagia incidence is reported to be lower with the adoption of less accurate and precise screening tests (37%-45%), higher when clinical tests are used (water swallow test, 51%-55%) and even higher when dysphagia diagnosis is based on instrumental tests (fiberoptic endoscopic evaluation of swallowing or videofluoroscopy, 64%-78%) [3].

Among the instrumental assessment tools, videofluoroscopic evaluation (VSE) and fiberoptic endoscopic evaluation of swallowing (FEES) are thought to be the current gold-standard. These techniques are equally sensitive to the detection of post-stroke aspiration and pneumonia and likewise useful in the evaluation of oropharyngeal dysphagia [38].

However, these tests have several practical limits. VFS is a relatively complex task both to perform and to interpret; test-test variability has been found within normal subjects undergoing this exam and interjudge agreement between different radiologists for VFS assessment can be very variable, probably reflecting their different skill or experience [39, 40]. Moreover for VFS to be undertaken, patients have to cooperate or at least be able to sit upright, which does not replicate physiological conditions. Further limitations are imposed by radiation exposure involved which, although regarded as acceptable, makes it an inappropriate test to repeat frequently to monitor changes [38].

Otherwise, FEES is a safe and well tolerated assessment conducted at bedside thereby allowing timely scheduling for both the endoscopist and patient [41, 42]; it is however an operator-dependent examination requiring both operator and specialized equipment expertise; besides it provides limited information about the oral and esophageal stages since aspiration cannot be seen directly, being inferred from residue left after swallowing or ejected after coughing [43].

Given the aforementioned limitations of those instrumental tools and considering that both VFS and FEES are not available in many clinical settings in which stroke patients are managed, there is a need of a valid, reliable, and feasible screening tool for the early assessment of dysphagia.

In this point of view, bedside clinical assessment of swallowing (BSA) has become a widely used initial test to identify those patients who would benefit from a more detailed assessment of their swallowing, such as VFSS or FEES [44].

By definition, this should be simple, quick to perform at bedside and sensitive enough to accurately identify stroke patients with risk of swallowing impairment. As a matter of fact a high sensitivity is required because of the increased morbidity and mortality associated with aspiration, which necessitates requirements for low false-negative results [1].

Nonetheless, the Joint Commission recently excluded swallowing screening as a performance measure for Primary Stroke Center certification [45]; moreover, although there are currently many bedside tests, clinical bedside assessment has been shown to miss up to 40% of those patients who aspirate; this is mostly because of the lack of systematically defined standards for what constitutes a valid swallowing screening tool, being still unclear which of these have the best psychometric and feasible properties and are easy to administer.

The following are the features most widely used in the literature as a part of the bedside evaluation of dysphagia.

Water Swallow Test (WST)

This test used water administered in various aliquots and ways as a trial swallow, while monitoring coughing and choking during and after swallowing. Indeed in the literature, the number of trials varied, together with water volumes administered which ranged from 5 to 150 mL. Different features has been also monitorized during WST, depending on the different study designs; Leder and colleagues found that the presence of 2 of 6 features (dysphonia, dysarthria, abnormal volitional cough, cough after swallow, abnormal gag reflex, and voice change after swallow) predicted greater dysphagia severity on VF [42]. When analyzing studies that used WST to evaluate aspiration and/or penetration [39, 44, 46-48], sensitivity ranged from 27% to 85%, while specificity ranged from 50% to 88% [49]. Several Authors [50-52] also used different viscosities textures (i.e., liquids, semi-solids and solids) while performing WST; although they reached an higher sensitivity and specificity, the assessment feasibility became lower because of the need of both considerable quantities of text materials and the time required for the test to be done.

Bulbar Function Assessment

WST effectiveness can otherwise be increased by careful assessment of bulbar function (i.e., abnormalities of pharyngeal sensation and reduced cough reflex, along with monitoring laryngeal elevation during swallowing. This is mostly because cough and wet voice in response to a WST, together with abnormal palatal sensation, are thought to be essential predictors of prolonged dysphagia [53], aspiration [1] and particularly useful in detecting silent aspiration [54].

Smithard and colleagues also identified weak voluntary cough after drinking different volumes of water, along with impaired consciousness level, as independent predictor for aspiration [39].

Moreover in acute stroke patients with dysphagia, a sensory deficit in the pharynx and supraglottic has been demonstrated by now. This sensory deficit is thought to play a pivotal role in the development of aspiration both directly, by reduced stimulus detection and discriminative capacity in the laryngopharynx, and indirectly, in impaired triggering of motor actions [53].

In this light many Authors searched for a reliable clinical or instrumental tool, which could allow a valid bulbar function assessment. Smith-Hammond and colleagues found that in stroke patients, objective measures of voluntary cough (i.e., duration, volume and peak flow of the inspiration phase, compression phase duration, peak flow and rise time for the expulsive phase, and volume acceleration) are strongly related to aspiration [55]; in this study it was also stated that subjective assessments of voluntary cough had otherwise poor performance.

Sensory capacity of the laryngopharynx has been also determined by endoscopically delivering discrete air pulse stimuli directed at mucosa innervated by the internal branch of

the superior laryngeal nerve. Given that air pulses test has been proven to detect laryngo-pharyngeal sensory deficits also in stroke patients with no clinical dysphagia [41], this examination might be essential for the detection of the so-called silent aspirators. Notwithstanding, it also appears to be not such a practical and reliable tool mostly because of it requires both an endoscopically delivered stimulus and an air pulse instrument.

Pulse Oxymetry and Silent Aspiration

Although pulse oxymetry has been criticized in the literature as a valid screening tool [56, 57], many studies focused on oxygen desaturation to evaluate aspiration/penetration since it has been shown to detect silent aspiration [44, 46, 52]. Depending on the decrease between the baseline oxygen saturation and the minimum saturation during the 120 sec, a pulse oxymetry decrease of greater than or equal to 2% has been widely considered as the endpoint. The sensitivity of this test so ranges from 56% to 87% while specificity from 39% to 97%, both depending on the different studies [39, 48]. Moreover, two different studies tested a combination of a swallow and oxygen desaturation test, by using coughing, choking, voice change or $\geq 2\%$ desaturation as the endpoints [44, 46].

With this paradigm, they reached a sensitivity of 94% and 98%, and a specificity of 63% and 70%, respectively [58]. In agreement with these data, in a recent review performed by Bours and colleagues it is stated that, by considering both the best psychometric properties and the feasibility of the screening methods, WST combined with pulse oxymetry (considering choking, coughing, voice change and desaturation $\geq 2\%$ as fixed endpoints), should be considered, to date, the most promising results as a screening tool in terms of validity, reliability and feasibility [49].

Nevertheless, although the most important international guidelines stress the importance of Screening of swallowing before the administration of food, liquid, or medication in patients with stroke, they do not recommend a specific screening method so far [59].

There is not even consensus in the literature, regarding either the best type of swallowing assessment to use, i.e., clinical or instrumental, or what specific characteristics acute stroke patients should have in order to benefit from either type of testing [42].

Hence WST appears as a simple tool, quick to perform at bedside and sensitive enough to identify stroke patients with risk of swallowing impairment.

CLINICAL AND NEUROANATOMICAL PREDICTORS OF POST-STROKE DYSPHAGIA

A recent study was conducted in order to assess clinical and neuroanatomical predictors of dysphagia following stroke [60]: the main purpose of the study was to investigate a sample of consecutive patients with ischemic and hemorrhagic stroke to evaluate incidence, prognosis, clinical and neuroradiological correlates of post-stroke dysphagia. Consecutive patients with acute ischemic or hemorrhagic stroke were consecutive recruited and followed-up after 14 days, in order to assess post-stroke swallowing impairment; according to the swallowing function, patients were then classified as: a) persistent dysphagic b) non-

persistent dysphagic or c) non-dysphagic. The role of leukoaraiosis in the pathogenesis, persistence and prognosis of post-stroke dysphagia is also discussed.

Patients who presented dysphagia were significantly older than those without; thus, elderly patients with stroke may have more swallowing alterations due to the reduced cough reflex and alteration of swallowing/ breathing coordination [61].

Dysphagia was influenced by the lesion size, but no differences were identified in the involvement of right or left hemisphere. In this view, the majority of studies performed on stroke patients did not observe any relation between the presence of dysphagia and side of hemispheric location [62-64]. However, it is known that lesions located in the right hemisphere may cause more pharyngeal changes and that lesions in the left hemisphere cause more changes in the oral phase of swallowing [65].

The NIHSS score at admission was higher in dysphagic patients. With this regard, the three different pattern of dysphagia (i.e., absent, transient or persistent) were compared over time regarding the stroke severity at admission, data from the ANOVARM after Tukey HSD post hoc analysis showed (Figure 1):

1. Patients with persistent dysphagia (PD) vs. patients with transient dysphagia (TD):
 - PD showed a significantly higher T0 and T1 NIHSS score with respect to both T0 ($p < 0.001$, $p = 0.023$ respectively) and to T1 ($p < 0.001$, $p < 0.001$ respectively) NIHSS scores of TD.
1. Patients with persistent dysphagia (PD) vs. no dysphagic patients (ND):
 - PD showed a significantly higher T0 and T1 NIHSS score with respect to both T0 ($p < 0.001$, $p < 0.001$ respectively) and to T1 ($p < 0.001$, $p < 0.001$ respectively) NIHSS scores of ND.
2. Patients with transient dysphagia (TD) vs. no dysphagic patients (ND):
 - TD showed a significantly higher T0 NIHSS score with respect to both T0 ($p = 0.002$) and to T1 ($p < 0.001$) NIHSS scores of ND, whereas T1 NIHSS of TD did not differ from both T0 ($p = 0.95$) and to T1 ($p = 0.38$) NIHSS scores of ND.

In other words, stroke severity was significantly higher in patients with persistent dysphagia with respect to those with transient dysphagia or without dysphagia, both at admission and at T1. Moreover, those patients with a transient pattern of dysphagia showed a sensibly improved NIHSS score at T1, which became similar, on average, to that of patients without swallowing impairment upon admission.

In the multivariable logistic analysis, stroke severity at admission was found to be an independent predictor of a persistent pattern of post-stroke dysphagia. The multivariable logistic model also allowed to represent ROC (receiver operating characteristics) curves and evaluate the predictivity of each significant variable using the AUC (Area Under the Curve) value. In this view, looking at ROC analysis, the T0 NIHSS score of 11.5 was found to be the best predictive value of persistent dysphagia, with a specificity of 90.1% and a sensitivity of 72.4%; the reported AUC was 0.898, which means that stroke severity at admission allowed to correctly classifying about 90 of 100 dysphagic patients in a persistent or non-persistent pattern. Hence, a $\text{NIHSS} \geq 12$ would be suggested as cut-off value in order to predict, upon admission, those patients who will probably remain dysphagic after 14 days follow-up. Figure 2 shows the ROC curves and the respective AUC.

Tukey post hoc analysis showed a significant difference between all groups (longitudinally compared among NIHSS) but: *p = 0.95, **p = 0.38. See the text for the details.

Figure 1. ANOVA for Repeated Measures.

AUC = Area Under the Curve.

Figure 2. ROC Analysis: persistent dysphagia.

Dysphagia was also more frequent in patients with hemorrhagic stroke; there are little available data in the literature reporting a different risk factor for dysphagia depending on stroke type. Paciaroni et al. [63] found, in a univariate comparison, an increased frequency of dysphagia in hemorrhagic stroke patients compared to ischemic ones. They suppose that it

could be related to stroke severity. Our results confirm this datum, since the Spearman's Rank Correlation revealed a strong statistical dependence between stroke severity at admission and hemorrhagic stroke. Looking at logistic regression analysis, the stroke type also appears an independent predictor for post-stroke dysphagia (OR 2.5); nonetheless hemorrhagic patients present a more than three-folded risk of persistent dysphagia. Hence, further research is needed in order to investigate a possible intrinsic mechanism linking dysphagia and hemorrhagic stroke.

Patients with high IQCODE score, which means a pre-stroke cognitive impairment, had more chances to present swallowing dysfunction; moreover, logistic regression analysis showed that the IQCODE score is an independent risk factor for post-stroke dysphagia and persistent dysphagia as well. These results are in agreement with previous reports which stated that brain lesions that cause decline in cognitive function, such as concentration and attention, may impair the control of swallowing [66].

Dysphagia was more frequent in patients with insular stroke, as well as in those with stroke involving frontal and temporal lobes, and basal ganglia. As a matter of fact, all the aforementioned structures are involved in the neural control of swallowing; in particular, insula is known to be closely connected both with cortical and subcortical pathways involved in the neural control of swallowing. Nevertheless, none of those structures was found to be an independent risk factor for dysphagia. In the case of insular stroke, this seems mostly due to the small number of pure insular stroke.

Otherwise, concerning the others aforementioned structures who failed to reach statistical significance once logistic regression analysis has been performed, this datum could suggest that cortical-subcortical pathways involved in the swallowing function are probably more important in causing dysphagia after stroke than a single structure "*per se*."

This hypothesis could be corroborated by analyzing the contributions of white matter to swallowing behavior. Interestingly, the Authors observed an independent correlation between post stroke dysphagia and leukoaraiosis severity as well as a strong association between leukoaraiosis and previous cognitive impairment. Recent studies reported that subcortical white matter connections play an important role in the pathogenesis of dysphagia: disruption of cortical-cortical and cortical-subcortical white matter connections seems to increase the risk of dysphagia and aspiration pneumonia by lowering the threshold of input to the medullary swallowing center.

These data, as well as those showing the role of a decline in cognitive function, suggest that swallowing impairment after stroke might be not just a simple pure motor disturbance, but also a more complex phenomenon. In this context, one might speculate that dysphagia may result from the combined effects of an acute focal damage and a preexisting impairment of the subcortical white matter connecting pathways. In other words, we might think of dysphagia as a kind of deficit in executive functions, which we know to be particularly associated with leukoaraiosis and cognitive disorders [67], and of course age [61].

Finally, pneumonia is among the most common medical complication after stroke, affecting up to one third of patients and accounting for nearly 35% of post-stroke deaths [2, 68]. Data from the aforementioned study [60] also suggest that stroke and pneumonia are associated with two-fold: on the one hand, pneumonia appears to be strongly linked to the presence of dysphagia at admission. In fact, among those patients who developed pneumonia during the entire hospitalization, 38 (93%) were dysphagic at admission. On the other hand, the persistence of dysphagia after 14 days was closely linked with the occurrence of

pneumonia ($p < 0.001$), with 36 patients (88%) with pneumonia who showed a persistent pattern of dysphagia.

RECOVERY FROM POST-STROKE DYSPHAGIA AND PERSISTENT DYSPHAGIA

The nervous system affected by a stroke damage is thought to reserve a variable ability to somehow reorganize damaged pathways and structures, allowing an effective recovery from swallowing impairment.

In this view, recent findings seem to suggest that the reorganization of cortical maps actually represents a central features in recovery from dysphagia after stroke.

In a MEG study Teismann and colleagues [69] analysed the swallowing-related activation areas both in stroke patients with dysphagia, in those patients without dysphagia and in healthy control as well. In the acute phase of stroke, it was described:

Patients with hemispheric stroke: while those patients without dysphagia reported an activation of the bilateral hemispheres, patients with post-stroke dysphagia are described to have a decreased cortical activation of the ipsilesional sensorimotor areas, and a near extinguished activation of the contralesional hemisphere; the whole sample of hemispheric stroke patients also showed an activation of the prefrontal cortex (BA 9) which was neither seen in healthy subjects nor in patients with brainstem stroke.

Patients with brainstem stroke: in both patients with and without dysphagia it was observed a reduced cortical activation, due to cortical compensation of a subcortical caused dysphagia, as well as a strong right hemispheric lateralization; the Authors speculated that this phenomenon may be related to “diaschisis.” This concept was developed by Von Monakow in 1914 and refers to the fact that the acute lesion may cause a damage of other areas functionally linked.

In healthy controls they observed a bilateral activation, mostly involving both the primary and supplementary motor cortex (BA 4 and 6). Other activation areas was represented by the primary and secondary sensory areas (BA 1, 2, 3, 4, 5, 6 and 7).

Hence, in conclusion, a strongly reduced cortical activation was bilaterally observed in stroke patients with dysphagia, probably due to an initial cortical shock after stroke.

What is absolutely remarkable, is that the activation of contralesional areas changed over time: in contrast to a strongly reduced activation in the acute phase, in the subacute phase of stroke (mean 12 days after stroke) this pattern changed to an increased brain activation of the contralesional hemisphere [69].

This datum seems to be crucial in order to understand the complex mechanisms leading to recovery from swallowing impairment after stroke.

In this point of view, it has been postulated that the recovery mechanisms from post-stroke dysphagia involve changes in neural networks already different from those described in the motor recovery after stroke.

After motor stroke, a reduced cortico-cortical connectivity in the affected hemisphere has been already described, as well as disinhibition phenomena (i.e., increased task-related BOLD activity) in the unaffected (i.e., contralesional) hemisphere [70]. Notwithstanding, the role of the contralesional primary motor cortex (M1) for motor recovery remain somehow

controversial: it is reported that enhanced activity in contralesional M1 might even exert a negative influence on the motor recovery of the paretic hand, probably due to transcallosal inhibition mechanisms between the primary motor cortex of both hemispheres. This “inter-hemispheric inhibition” is otherwise confirmed by several TMS-fMRI studies which show that stroke patients with motor impairment may benefit from contralesional M1 inhibition [71]. Hence, it is suggested that a strong engagement of the unaffected hemisphere may represent an indicator of inefficient cortical reorganization, thereby exerting a detrimental effect on motor recovery after stroke.

On the contrary, recent data shows that recovery from post-stroke dysphagia follows a reorganization of the unaffected motor cortex.

Hamdy and colleagues [72], by coupling fMRI analysis with TMS-evoked EMG responses, described a different compensatory reorganization between hemispheres during the recovery of swallowing and limb function: while improvements in limb function were associated with an increase in cortical representation in the damaged hemisphere, patients who recovered from dysphagia, showed an increased pharyngeal representation in their cortical maps over the unaffected hemisphere, both at one and at three month after stroke, without change in the affected hemisphere [37,62]. In contrast, those patients who remained dysphagic, did not show any variation in their pharyngeal map.

The most interesting findings is that this cortical change seems to appear before any improvement in swallowing function, suggesting that the change in cortical excitability for pharynx is not merely the consequence of the normal swallow activity resumption, but it actually represents the drive for dysphagia recovery.

Moreover, they also found that pharyngeal responses from the unaffected hemisphere showed a marked increase in both the amplitude and area of representation over time, without concurrent shift in latency; this datum suggest an alteration in the excitability of cortex rather than more caudal brain regions, such as brainstem central pattern generator or bulbar motoneurons.

It is intriguing that it was also described a different compensatory reorganization between hemispheres during the recovery of swallowing and limb function.

It could be then speculated that this finding supports the hypothesis of a bilateral and asymmetric representation of swallowing: since swallowing musculature, unlike limb musculature, is represented on both hemispheres, although a damage to the dominant hemisphere for swallowing may cause dysphagia, there remains within the intact hemisphere the capacity for reorganization, by exerting a sufficient control over brainstem centers to drive swallowing recovery.

Notwithstanding, about half of stroke patients remain dysphagic after seven days from symptoms onset, and approximately 13-15% [73] of patients has persistent dysphagia after six months.

To date, it is unclear why some stroke patients develop a persistent swallowing impairment after stroke or, in other words, if the failure in recovery from dysphagia is due to a stroke involving the dominant swallowing hemisphere, rather than a swallowing key region, or even to a less efficient contralesional hemisphere activation, perhaps due to an insufficient bilateralism in cortical representation of swallowing.

In this view, many efforts have been made in order to identify those patients who are at high risk for developing a persistent dysphagia after stroke, and therefore to identify those patients who may benefit from a more detailed assessment of their swallowing function.

Nevertheless, clinical and neuroradiological correlates of post-stroke dysphagia remain still unclear, and even fewer data are available on predictors of persistent dysphagia so far.

Dt. Massimiliano Toscano, MD, PhD

2005 Medical Degree, University of Rome “La Sapienza,” summa cum laude

2013 Residence in neurology, Dept. Neurological Sciences, University of Rome “La Sapienza,” summa cum laude

2016 PhD in Behavioural Neuroscience, Dept. Neurological Sciences, Dept. of Psychology, University of Rome “La Sapienza”

Present Appointments And Previous Experience

2015-present: Research Assistant, Dept. Neurological Sciences, University of Rome “La Sapienza”

2013-present: Guest Neurologist of the Stroke Unit and the Headache Clinic, Dept. Neurological Sciences, University of Rome “La Sapienza”

2013-present, Neurologist of the rehabilitation clinic A.N.F.F.A.S. Rome onlus.

2013-2014, Lecturer in Clinical Neurology, learning related mechanisms and disability, I.R.S.E.F. Research Institute

2005-2008 Guest doctor Stroke Unit and the Headache Clinic, Dept. Neurological Sciences, University of Rome “La Sapienza”

2005-2007 Lecturer in Clinical Neurology. Graduating Course in Speech Therapy, University of Rome “Tor Vergata”

Research Focus

Cerebrovascular diseases (post-stroke dysphagia, pathophysiology of stroke in the acute phase, mechanisms of recovery post-stroke, clinical application of functional neuroimaging techniques, neurosonology, psychiatric comorbidity)

Behavioural Neuroscience (Behavioural Neurophysiology, Learning related mechanisms and disability, Speech related mechanisms, Neurophysiological correlates of Psychiatric diseases)

Pain (morphofunctional correlates of pain in humans, pathophysiology of primary headaches, migraine, psychiatric comorbidity)

Other Activities

Member of the ESNCH (European Society of Neurosonology and Cerebral Hemodynamics) and the SISC (Società Italiana per lo Studio delle Cefalee)

Member of the Executive Committee of the SISS (Società Italiana per lo Studio dello Stroke)

Member of the Executive Committee of the I.R.S.E.F. Research Institute

Prof. Vittorio Di Piero, MD, PhD

1979 Medical Degree, University of Rome “La Sapienza,” summa cum laude

Present Appointments And Previous Experience

2000-present Associate Professor of Neurology, Dept. Neurological Sciences, University of Rome “La Sapienza,” executive coordinator of the Stroke Unit and the Headache Clinic

1989-2000 Senior Registrar - Dept. Neurological Sciences, University of Rome “La Sapienza”

Visiting Appointments

1988-89 Honorary Research Fellow, Royal Postgraduate School, Hammersmith Hospital, London

1984-85 Research Fellow, Dept. Biomedical Technologies, Istituto S. Raffaele, Milan

Research Focus

Cerebrovascular diseases (pathophysiology of stroke in the acute phase, mechanisms of recovery post-stroke, clinical application of functional neuroimaging techniques)

Aging and dementia (cognitive decline and its clinical and morphological correlates, perfusional derangements during degenerative and vascular dementia)

Pain (morphofunctional correlates of pain in humans, pathophysiology of primary headaches, migraine, psychiatric comorbidity)

Other activities

Member of the European Neurological Society;

the International Stroke Society;

the European Stroke Council; the International Association for the Study of Pain;

the Società Italiana di Neurologia and the Società Italiana per lo Studio delle Cefalee.

Member and President Elected of the Executive Committee of the Società Italiana per lo Studio dello Stroke, and the Associazione per la promozione delle Ricerche Neurologiche.

ABSTRACT

Impairment of empathy or social-emotional functioning are a disabling central feature in right hemisphere stroke, for which there is currently no proven effective treatment. Oxytocin may be a viable treatment to ameliorate this deficit. A decade of oxytocin research in humans has shown us that the hormone may not have prosocial effects in all situations across all people. Care must be taken to ensure that factors that influence its effects are addressed in a treatment paradigm. Long term oxytocin treatment paired with social cognitive training in a controlled clinical setting may prove to be an effective implementation of the peptide. Future work may have to consider problems in current statistical analysis, oxytocin delivery, and understanding of gender effects.

INTRODUCTION

The importance of empathy in our lives is apparent. It plays a role in nearly all human social interactions and is critical in the maintenance of close human relationships. Impairments in empathy have been well-documented in several neurological and neuropsychiatric diseases such as autism, schizophrenia, frontotemporal dementia, and traumatic brain injury (Baron-Cohen et al., 1985; Sacks et al., 2013; Hillis, 2014). With some

of the earliest reports appearing in the late 1970s into the 1980s, patients with right hemisphere stroke have also been reported to have a range of pragmatic social deficits from difficulties with prosodic recognition and production to impairments in theory of mind and perspective taking (Hier et al., 1983). These deficits can have negative consequences such as social isolation or decreased marital satisfaction that may impact quality of life (Blonder et al., 2012). In a 2014 study from our Stroke Prevention and Recovery Center, residual impairment empathy was found to be one of the top concerns for 50% of spouses or adult children of right hemisphere stroke survivors (Hillis and Tippett, 2014). This impairment may also prevent patients from accessing familial social support, which worsen long term outcomes of patients (Grant et al., 2006). Despite the apparent impact and importance of empathic deficits, there are currently limited proven treatments available for right hemisphere stroke patients.

In considering a potential treatment for social-emotional deficits, the goal of such a treatment must be clearly defined. From our perspective, a treatment for these deficits should ideally return patients to a state where they can make emotional and prosocial decisions the same way that they were made before the stroke. In essence, an ideal treatment should fully repair the damage done by a stroke to the social functioning of a patient and return that patient to a pre-stroke functioning level. To this end, physiological and psychological experience of emotions must be fully restored along with social-cognitive functions where deficits exist. Actions beyond this are not within the scope of the neurological perspective presented here and fall under the purview of psychology and psychiatry.

Our aim in this chapter is to introduce oxytocin as a potential treatment option to accomplish this goal of the restoration of social cognitive functioning after stroke. We will begin with some background on stroke and a discussion of empathy. Afterwards, we will transition to a discussion of oxytocin research in humans, its potential benefits for stroke patients, and practical considerations that are needed to plan a future oxytocin clinical trial.

OVERVIEW OF RIGHT HEMISPHERE STROKE

A stroke is defined as a sudden focal neurological deficit due to a disruption in the blood supply to a specific area of the brain. Approximately 795,000 people each year experience a stroke in the United States, and stroke is a leading cause of long-term disability (Mozaffarian et al., 2015). Disruption of blood flow in stroke caused by vessel blockage, known as ischemic stroke, accounts for 87% of cases (Grysiewicz et al., 2008). Stroke is also caused by blood vessel rupture, known as hemorrhagic stroke, which accounts for the remaining cases.

Due to the lateralization and functional organization of the brain, lesions caused by stroke can cause dramatically different deficits depending on the brain structures and hemispheres affected by the stroke. For instance, speech and language issues are most common in patients with left hemisphere stroke and are not as prevalent in patients with right hemisphere stroke, with the precise deficits being further dependent on the exact left hemisphere regions affected (for review see Hillis, 2007). In contrast, deficits in visual and spatial processing are very common in patients with right hemisphere but not as prevalent (or at least not as severe) in left hemisphere stroke patients (Hier et al., 1983). The focus of this chapter will be on empathic deficits common in patients with right hemisphere stroke (Happé et al., 1999).

Despite these differences, left and right hemisphere stroke patients often experience some more ubiquitous symptoms in the form of contralateral paralysis and some generalized cognitive deficits, though the extent of these symptoms are highly variable between patients (Mozaffarian et al., 2015).

The deficits incurred as a result of stroke are by no means static. Considerable plasticity leads to spontaneous recovery across cognitive, sensory, and motor domains (Langhorne et al., 2009; Sebastian et al., 2016; Murphy and Corbett 2009). A significant amount of the current research on stroke recovery focuses on understanding, predicting, and enhancing the brain's natural ability to repair damage. Treatment approaches that may stimulate this activity such as transcranial direct current stimulation (tDCS), medications, and behavioral therapies (often in combination) are currently being tested as a way to enhance recovery (Shlaug et al., 2008; Baker et al., 2010).

DEFINING EMPATHY

Given the highly subjective nature of empathy, it is important to first understand how empathy is characterized by psychologists and cognitive neuroscientists. Much of the non-human primate and developmental literature has split empathy into two separate components: an affective component and a cognitive component (Shamay-Tsoory, 2010).

The affective component, an evolutionarily conserved feature in much of mammalian lineage, encompasses simple emotion recognition skills and a phenomena known as emotional contagion (Ze et al., 2014). Emotional contagion describes a process where an individual's emotional state will shift towards the perceived affective state of another person (Melloni et al., 2014). It is believed that emotional contagion can occur without an explicit cognitive attribution of the acquired affective state to another person or an explicit understanding of why the other person is displaying a specific affective state. For instance, a young child may cry if someone around them is clearly upset, but they may not be aware of the reasons underlying the other person's feelings and they may not attribute the source of their own sadness to the other person.

In contrast, the cognitive component of empathy has been conceptualized as a uniquely human or uniquely primate element of empathy that involves more intricate cognitive understandings of another's emotional state (Shamay-Tsoory, 2010). It is contingent on an ability known as theory of mind, which is the ability to understand the mental state of another as separate from one's own emotional state with independent goals, intentions, and feelings. Cognitive components of empathy encompass knowledge of the cause of another person's emotional state and an understanding of the implications of that state (Hillis, 2014). If emotional contagion is an "early" form of empathic ability, the cognitive aspects are more akin to the complex social-emotional reasoning that we see develop as a person develops from child to adult.

However, it is our view that neither the affective nor cognitive components of empathy operate alone during real-world social interaction in adults. This is because nuanced human empathic reactions to social situations involving other people are predicated on a complex interaction between these two components (Ochsner and Gross, 2005). For example, the response evoked during emotional contagion can be modified based on cognitive insight and

perception, and an affective state evoked via contagion can similarly modify our cognitive interpretations. Given this simultaneous feedback between cognition and contagion, we combine affective and cognitive empathic skills into a single but multicomponent construct, which we term emotional empathy. Emotional empathy is then a unitary experience of empathy that is the sum of the interaction of affective and cognitive components of empathy and the underlying processes of those two constructs.

Considering this broader and more encompassing view of emotional empathy as a single entity rather than as two separate constructs is key in the context of discussing prosocial behavior and social functioning in right hemisphere stroke patients. Though the link between empathy and prosociality is beyond the scope of this chapter, it is reasonable to assume that a disruption in either contagion or perspective taking would cause some information or motivation to be lost especially because of the interaction between the two (Bzdok et al., 2012). Thus, a return to premorbid social functioning is contingent on ensuring recovery of the full spectrum of emotional empathy. While the exact nature of premorbid social functioning will be different for each patient, a reorganized and effective neural system for emotional empathy will be necessary to ensure that similar social decisions can be made as they were before.

It is important to note that it is possible for right hemisphere stroke patients to experience social functioning deficits that are not due to damage to emotional empathy *per se*. The most common example in this patient population is aprosodia. Prosody refers to elements of spoken language such as timing, loudness, stress, or frequency modulation that affect dramatically the meaning of what is said (Ross and Monnot, 2008). Right hemisphere stroke generally disrupts expression or recognition of affective prosody—prosody that communicates the feelings of the speaker or their attitude (Blonder et al., 2005). Deficits in recognition and production of affective prosody have been shown to cause communicative difficulties that and can strain personal relationships (Blonder et al., 2012). As one might imagine, not being able to easily extract affective prosodic information could result in less information reaching the emotional empathic process though the impaired social interaction is not due to an empathic deficit *per se*. In addition, if a patient is unable to convey prosodic affective information in speech they may sound apathetic even if they are not. A parallel process may occur with impaired recognition or display of facial expressions, where a patient would face difficulties with empathic functioning that do not arise from a strictly empathic deficit. Thus, loss of function in either emotional information input or emotional expression output can pose major issues for the social functioning of patients. Given this conception of empathy and empathic deficits, let us turn our attention to a discussion of the modern understanding of oxytocin. If we aim to use oxytocin as a treatment, we must first understand how it functions.

TOWARDS A NUANCED UNDERSTANDING OF OXYTOCIN

Oxytocin is a peptide hormone released by the posterior pituitary that has historically been commonly associated with its biological role in mammalian childbirth and lactation. However, early work also showed that the hormone also appears to influence mammalian animal behaviors such as maternal behavior and pair-bonding (Pedersen & Prange, 1979;

Pedersen et al., 1982; Williams et al., 1994). These early studies in rats and prairie voles were able to establish the link between oxytocin and behavior because they could directly inject oxytocin into central nervous system structures and observe behavioral changes. Similar results have been replicated in other mammals such as sheep and non-human primates (Costa et al., 1996; Smith et al., 2009). Given these strong results, interest in oxytocin's potentially prosocial effects in humans has rapidly grown over the past two decades. Unfortunately, many of the methodologies used in animal work involved invasive surgeries that were not appropriate for human use. This challenge was overcome when it was found that oxytocin inhaled intranasally could increase central nervous system levels of the peptide hormone (Born et al., 2002).

Since the discovery of the effects of intranasal oxytocin, the number of oxytocin studies in humans has increased considerably. One of the first major studies came in 2005 from Kosfeld et al. with the discovery, in a double-blind placebo-controlled study, that intranasally administered oxytocin may facilitate trust in humans. Their experiment, known as a trust game, involves an "investor" participant and a "trustee" participant each starting with a certain amount of money. The investor can then choose to transfer some of their capital to the trustee. Any money transferred to the trustee triples in value, meaning that the trustee would receive 24 monetary units if they were given eight. At this point, the trustee can choose how much to transfer back to the investor, if anything. The game poses a dilemma for the investor because their trust in the other player could result in ending the game with less money than they started the game with. Importantly, Kosfeld et al. found that investors who were administered oxytocin were more likely to offer more money to trustees than investors given placebo. The authors argued that these data showed increased trust behavior on the part of the investors. This paper had a major impact on the field because it showed that administering oxytocin could produce prosocial effects.

Several other studies published around the same time found similarly prosocial effects. For instance, Domes et al. (2007) found that oxytocin was able to increase the ability to infer internal states based on pictures of the eye region of faces in the Reading the Mind in the Eyes Test (RMET), a key empathic skill set. Early fMRI work suggested that oxytocin's effects may be due to down-regulation of the amygdala, decreasing activation to produce an analgesic effect that promotes social approach behavior (Kirsch et al., 2005; Domes et al., 2007b). A study showing the early promise of oxytocin as a treatment option in neuropsychiatric disorders found that oxytocin facilitated processing and retention of social information in patients with autism (Hollander et al., 2007).

Taken together, these results painted a very optimistic picture of oxytocin that would drive research and popular perception into our current decade. The findings of many of these early oxytocin trials suggested a very broad range of prosocial effects hence perceptions of oxytocin as a "moral molecule" or "prosocial peptide". In recent years, the field has since shifted away from this perception with many questioning this overly simplistic characterization of oxytocin as a kind of "social panacea" (Bartz, 2016). One of the major concerns raised by the current literature revolves around the fact that large scale meta-analyses show a great deal of inconsistency in results across studies. Null results or even antisocial results are obtained in oxytocin trials too frequently in the literature to be explained solely by random error (Bartz et al., 2011b; Bartz, 2016). In addition to these concerns, other authors raise issue with statistical and methodological aspects of individual oxytocin studies (Walum et al., 2016; Lend and Ludwig, 2015).

While the plurality of oxytocin's observed effects is not yet fully understood, there is some consensus on a three pronged model presented by Bartz, Zaki, Bolger, and Oschner in their seminal 2011 review. Bartz et al. present the wide spectrum of results from null to prosocial to antisocial as being explainable under three different mechanisms. The first proposed mechanism is that oxytocin may act as an anxiolytic, reducing social anxiety and increasing prosociality through this action. It is important to note that this cannot easily explain the antisocial effects of oxytocin and increases in performance on some social cognitive measures. The second mechanistic proposal is that oxytocin activates a desire to affiliate with others. This mechanism would explain increased social cognitive performance and leaves room for context dependent and person-dependent effects. The third proposed mechanism is that oxytocin increases the salience of social stimuli. This would essentially enhance cognitive access to social-emotional information; the context under which the information is received and individual social strategies would likely modulate the response.

Though many critics of the circa 2007 view of oxytocin cite the contemporary view as a major departure from the "prosocial peptide" era the complexity of the effects of oxytocin were alluded to in the early human literature. For instance, in the Kosfeld trust study, the investigators reported that oxytocin increased the trust of the investors, but oxytocin administration did not increase the generosity of the trustees when deciding how much to transfer back to the investors. Here, it is clear that oxytocin was not a blanket prosocial drug that increased all positive social behavior. For the Domes et al. study, though it is often referred as a study that showed universal increased emotional inference ability on the RMET upon oxytocin administration, the effect of oxytocin was only significant for items considered to be very difficult. The overall significant increase in performance was driven by the more challenging items with no significant difference in performance on simpler items. For this reason, these results imply that administering oxytocin may not actually impact simple and routine empathic judgments that a person frequently encounters, demonstrating a narrower effectiveness for the peptide. Ultimately, these original studies should be taken as a proof of concept that oxytocin can have prosocial effects. Further work on oxytocin has revealed important context dependence and person-dependent nature of its effects.

A paper published in 2010 by Declerck, Boone, and Kiyonari is perhaps one of the most well-known examples of the context dependence effect. In this study, participants played two monetary games, one that encouraged cooperative action and one that was structured as a prisoner's dilemma. In the cooperative action game, theoretically the best possible outcome for either player would be if both cooperated, and choosing a selfish action would result in a less favorable outcome for both players. In the prisoner's dilemma, choosing the selfish action results in the best outcome leaving little incentive to cooperate. A key aspect of the study is that half the participants were allowed to meet their partners for the game beforehand, while the other half were not. As expected, participants were overall less likely to cooperate in the prisoner's dilemma scenario compared to the cooperation scenario. However, oxytocin actually decreased the willingness to cooperate for players who had not met their partners in both games. For players that had met their partners beforehand, oxytocin increased their likelihood to cooperate, though this effect was very small for the prisoner's dilemma game. In essence, Declerck et al. showed not only that oxytocin likely requires social familiarity in order to have a prosocial effect but also that the absence of this familiarity renders oxytocin's effects antisocial. Moreover, oxytocin administration was not sufficient to significantly boost cooperativity among players in the prisoner's dilemma game, where it is not logical to choose

to cooperate. As others have cast similar results, “oxytocin makes people trusting, not gullible” (Mikolajcak et al., 2010).

Results such as these foreshadowed a body of literature that demonstrates an antisocial side to oxytocin (Zik and Roberts, 2015). In adult patients with borderline personality disorder, oxytocin administration has been shown to decrease the likelihood of trust and cooperation in a social dilemma game similar to the tasks described in the preceding paragraph (Bartz et al., 2011a; Ebert et al., 2013). In adults with trait physical aggressiveness, oxytocin administration was found to increase intimate partner violence inclinations (DeWall et al., 2014). Additionally, oxytocin has been shown to promote human ethnocentrism, a potential source of prejudice, xenophobia, and racial bias (Dreu and Greer, 2011; Sheng et al., 2013). Taken together, these data show that oxytocin can promote less than desirable behaviors especially for individuals with a propensity for maladaptive social responses. The significance of this pertaining to the use of oxytocin as a treatment in right hemisphere stroke is apparent. These data suggest that simple administration of oxytocin to patients is unlikely to produce the consistently prosocial effects that we would need from a viable treatment for social-emotional deficits in right hemisphere stroke. More than likely, oxytocin treatment will need to more carefully structure the environment under which oxytocin is administered to account for the full range of possible responses from prosocial to antisocial.

OXYTOCIN AND EMOTIONAL EMPATHY IN THE BRAIN

Thus far our discussion of oxytocin and empathy has been limited to a behavioral perspective, but imaging studies of healthy controls and patients with neurological disease have identified a set of key brain areas that are involved in emotional empathy and the oxytocin response. Three key areas in particular have emerged as a major sites of oxytocin action within the emotional empathy network: the insula, the temporal pole, and the amygdala.

The insula is an area of the brain known to be involved in perception of another person's emotions, especially negative emotions and pain (Singer et al., 2004; Chakrabarti et al., 2006; Gu et al., 2012; Bernhardt and Singer, 2012). In a group study of 27 patients, Leigh et al. (2013) found that lesions in this area were significantly associated with impaired performance on a test of affective perspective taking in acute stroke patients. Another study with a sample of combat veterans with focal traumatic brain injury similarly found a correlation between insular damage and decreased self-rated emotional empathy (Driscoll et al., 2012). In oxytocin imaging studies, it has been found that oxytocin increases activity in the insula in response to emotional stimuli such as infant crying and during tasks such as the RMET for patients with clinical depression (Riem et al., 2011; Pincus et al., 2010). Taken together, the data suggest that the insula plays a role in many of the component processes and damage to the region will likely detrimentally affect emotional empathy and social functioning as a whole (Hillis, 2014).

A second brain area identified as central to emotional empathy is the temporal pole. In a study mentioned earlier, Leigh et al. (2013) also found that all acute stroke patients tested that had damage in the right temporal pole had impaired empathy. Moreover, extent of the damage to the region was significantly correlated with errors in affective perspective taking. In

behavioral variant frontotemporal dementia, a neurological disorder characterized by disturbances in social functioning, the degeneration of right temporal pole has been found to be correlated to the level of social dysfunction observed (Rascovsky et al., 2011; Rankin et al., 2006). Functional imaging studies in healthy controls have corroborated these results as well showing that the temporal pole plays a role in affective perspective taking (Meyer et al., 2013). There is some evidence to suggest that oxytocin modulates activity in this region albeit more limited than the evidence connecting oxytocin to the insula and the amygdala (Domes et al., 2007; Domes et al., 2013).

The amygdala is the third area shown to be a major point of intersection between oxytocin and the emotional empathy network. Two activation likelihood estimation meta-analyses, one focused on empathic behavior and another focused on empathy for pain, both found that the amygdala was an area consistently associated with empathy (Bzdok et al., 2012; Gu et al., 2012). In the Leigh et al. (2013) study, acute stroke patients with lesions in the right amygdala showed impairment in affective perspective taking. Similar impairment was found in a previous study of two patients with acquired bilateral amygdala lesions (Stone et al., 2003). It is likely that the amygdala plays a role in both the affective and cognitive components of empathy with lesions leading to a major disruption in social cognitive functions and physiological manifestations of emotion (Hillis, 2014).

The amygdala is of particular interest when considering oxytocin's potential as a treatment for right hemisphere stroke. There is a robust body of evidence that oxytocin modulates amygdala activity; many of the imaging studies discussed in this chapter converge in support of this proposal (Domes et al., 2013; Bethlehem et al., 2012; Labuschagne et al., 2010; Riem et al., 2011). However, perhaps the most intriguing link between oxytocin and the amygdala is their relationship in socially reinforced learning. In a landmark double-blind study, Hurlemann et al. (2010) found that oxytocin administration increased learning performance on a feedback-guided item-category association task when social reinforcers were used as feedback. Moreover, they showed that this effect is amygdala dependent by demonstrating that two individuals with bilateral, congenital damage to the amygdala (Urbach-Wiethe disease) were not able to effectively learn through this pathway. This effect will require further study, but it does appear to have a basis at the synaptic level and the MAP kinase signaling cascade (Lin et al., 2012; Tomizawa et al., 2003).

ENVISIONING OXYTOCIN TREATMENT FOR RIGHT HEMISPHERE STROKE

To summarize, our goal is to explore the possibility of oxytocin treatment for social-emotional deficits in right hemisphere stroke patients that may involve issues with receiving, processing, and/or expressing affective or social information. The literature has established the context-dependence and individual factors that may influence the effects of oxytocin, and we have a few key brain areas that oxytocin is likely to modulate (Bartz et al., 2011b; Hillis, 2014).

From the very outset, while the vast majority of oxytocin experiments or treatment studies to date involve single doses. From these studies, the lasting benefits of single dose for patients with neuropsychiatric disorders with significant social-emotional impairments seem

questionable (Bartz, 2016). The loss of brain tissue due to stroke can cause severe deficits across a full spectrum of functions, requiring many months for recovery that is often incomplete (Frost et al., 2003). It is implausible that a single dose of a naturally occurring brain peptide hormone could lead to the dramatic neural reorganization needed to reverse damage caused by a large stroke. Nevertheless, treatment studies such as Jesso et al. (2011) in frontotemporal dementia patients should be taken as a proof of concept that warrant further study for long-term oxytocin treatment (Finger et al., 2014). To be truly useful in improving prognosis for stroke patients, oxytocin should be administered over the long term if it is to have an appreciable lasting effect.

This conclusion brings up an important consideration about the conditions under which oxytocin is administered and to whom it would be administered. As discussed earlier, oxytocin's effects are notoriously context and person dependent. If oxytocin is administered in an uncontrolled manner, it could induce antisocial behaviors that would be counterproductive to treatment aims. Moreover, it is possible that stroke patients may have preexisting psychiatric conditions such as borderline personality disorder that could cause oxytocin to worsen social functioning (Ebert et al., 2013). Many stroke patients develop depression during the recovery process. The potential interaction between depression and oxytocin will need to be further evaluated and considered (Hackett et al., 2005). In the context of stroke care, many patients stay in the hospital for extended periods and undergo inpatient rehabilitation for even longer periods. The best way to control the context under which oxytocin is administered and to monitor for adverse responses may be to integrate the treatment into these established clinical frameworks rather than allowing unmonitored use at home. The patient would likely need to feel supported and safe in order to observe the more positive effects seen in the Kosfeld era literature.

In the hospital setting, the effectiveness of oxytocin treatment could be increased if paired with another therapy such as social cognitive training. Trust is not built in a day and the pair-bonding effects of oxytocin are likely due to chronic exposure or elevation of central levels. The same could be said of social cognition and social functioning, with some authors proposing that social cognition be thought of as reinforced learning based on feedback from others (Zaki et al., 2016). In this view, social cognition is an adaptive process where we make inferences and then adjust them based on available feedback information. Social cognition is then less about the immediate accuracy emphasized in many tests (e.g., Reading The Mind In The Eyes Test) and more about a kind of adaptive accuracy. Given oxytocin's role in amygdala-dependent social learning, oxytocin may enhance this adaptive process through that pathway (Hurlemann et al., 2010). By encouraging this learning through social cognitive training, oxytocin may be able to facilitate recovery of social functioning more effectively. In other words, the amygdala-dependent learning pathway may be a vehicle to access plasticity that could enhance recovery of social function in right hemisphere stroke survivors. Given that the learned stimuli used by Hurlemann et al. were not explicitly emotional per se, it is likely that other abilities could be reinforced through oxytocin administration as well.

The benefits of oxytocin treatment may even extend beyond simply retraining social cognitive functions to strengthening the patient treatment alliance. Trust is an important component of the treatment alliance as it is critical that stroke patients trust their doctors and their caregivers. Social cognitive impairments may strain relationships between these three entities and decrease quality of care as a result. Notably, we have found that 50% of caregivers of right hemisphere stroke survivors cite empathic deficits as one their top five

concerns, which was more frequent than motor or sensory deficits (Hillis and Tippet, 2014). Given a positive social context, oxytocin may be able to address some of these empathic concerns and strengthen the trust between caregiver and patient (Meyer-Lindenberg et al., 2011; Lieberwirth & Wang, 2014). This effect of oxytocin on the treatment alliance has been observed in other clinical populations, which suggests that it may work in stroke as well. For instance, in a two-week pilot study of intranasal oxytocin for cocaine-dependent patients receiving methadone treatment, Stauffer et al. (2016) found that oxytocin caused patient reporting of drug use to more closely match the results obtained from urine testing, a result that the authors speculate could indicate increased trust. In individuals with post-traumatic stress disorder, it has been shown that oxytocin can normalize abnormal insula and putamen responses to social reward, which may stabilize social relationships in the treatment alliance over time (Nawijn et al., 2016).

CONSIDERATIONS FOR FUTURE OXYTOCIN TREATMENT RESEARCH

Two of the major concerns about current oxytocin research are statistical rigor and the method of delivery of intranasal oxytocin itself (Walum et al., 2016; Leng and Ludwig, 2015). Both of these articles argue for an increase in the statistical rigor of future oxytocin studies. At least some of the inconsistencies across studies can be explained by low power and inappropriate statistical methods in some studies, although some inconsistencies are likely due to context effects. Compliance with uniform standards, such as clearly defining outcome variables and specifying statistical analyses beforehand will no doubt increase the quality of future research. Healthy skepticism should be used when approaching oxytocin data, understanding that single dose effects in an experimental context should not necessarily generalize to a wide array of indiscriminate prosocial behaviors. Technical innovations may also be needed in the current method of delivering oxytocin intranasally, which to date is still not fully understood (Leng and Ludwig, 2015; Guastella et al., 2013). Large amounts are delivered via nasal sprays, but the mechanism and consistency of what occurs once the oxytocin reaches the nasal epithelium is unclear. Better methods of delivery may be needed to improve consistency in oxytocin trials.

Another important consideration for future oxytocin research in stroke patients is gender differences in oxytocin's effects. Much of the research covered in this chapter used samples primarily composed of males, and the effects may be different in women (e.g., Hurlemann et al., 2010; Kosfeld et al., 2005). Gender differences are likely given that the literature suggests that oxytocin's effects are indeed sexually dimorphic (MacDonald, 2013). Despite the strength of the evidence for a role of oxytocin in attachment in females, there are likely some undiscovered nuances (Bartz, 2016). Future research should account for individual differences as well as differences across sexes and ultimately adjust treatment accordingly.

CONCLUSION

Our understanding of oxytocin has advanced well beyond initial conceptions to include its significant context- and person-dependent effects. There still remains much work to be done before oxytocin will be ready to be integrated into standard practice in the clinic for use as a therapy in right hemisphere stroke patients. In particular, long-term trials will be needed to test the safety, efficacy, as well as the feasibility of using the treatment with social cognitive training, ideally during inpatient rehabilitation. Oxytocin presents considerable promise as a treatment option for stroke patients, but results will have to be considered with a new lens of nuance and systematic scientific rigor.

BIOGRAPHICAL SKETCH

Name: Charlten Long

Charlten Long is a senior undergraduate student at Johns Hopkins University, where he majors in neuroscience. Charlten Long is currently a research assistant in Dr. Argye Hillis' Stroke Cognitive Outcomes Lab (S.C.O.R.E.), where he has worked for 3 years. As a recipient of a 4-year JHU Woodrow Wilson Undergraduate Research Fellowship, he established an innovative clinical trial, a collaborative study between JHMI and UCSF, aiming to use computerized training to treat social-emotional deficits in patients with right hemisphere stroke and frontotemporal dementia. Additionally, he contributes to an ongoing longitudinal fMRI study of language recovery after stroke. A native of California's Bay Area, Charlten previously worked in the labs of Dr. Sophia Vinogradov and Dr. Joshua Woolley. Working with Dr. Vinogradov, he received experience in researching the use of cognitive and social cognitive training in patients with schizophrenia. Charlten's work in Dr. Woolley's Bonding and Attunement in Neuropsychiatric Disorders Lab first exposed Charlten to the study of the effects of oxytocin administration for patients with schizophrenia. Charlten is interested in a future career of translational research searching for novel treatments to improve cognitive and functional impairments in patients with chronic neurological disorders.

Name: Argy E. Hillis

Argye E. Hillis is a Professor of Neurology, Physical Medicine & Rehabilitation, and Cognitive Science at Johns Hopkins. She serves as the Executive Vice Chair of Neurology, and Director of the Cerebrovascular Division. She began her career as a Speech-Language Pathologist and Director of Neurological Rehabilitation, focusing on studies of novel treatments of aphasia and communication disorders after right hemisphere stroke. She also studied Cognitive Neuropsychology in the Cognitive Science Department at Johns Hopkins, where she later became a faculty member. Her research focused on identifying the cognitive processes underlying language and spatial representations through the study of aphasia and hemispatial neglect, and how these investigations might help focus rehabilitation. Dr. Hillis then completed medical training and neurology residency at Johns Hopkins, and integrated her training in the fields of Speech-Language Pathology and Cognitive Science with Neurology to continue her investigations of aphasia and right hemisphere cognitive and

communicative impairments and how they recover. Her research combines longitudinal task-related and task-free functional imaging and structural imaging with detailed cognitive and language assessments to reveal the dynamic neural networks that underlie language and cognitive functions, such as empathy and prosody. Her lab studies changes from the acute stage of stroke through the first year of recovery, to improve our understanding how language and other cognitive functions recover after stroke and how to facilitate recovery. One study evaluates the effectiveness of transcranial direct current stimulation (tDCS) as a method of augmenting structured language therapy. The Hillis lab also studies Primary Progressive Aphasia, and how to reduce the rate of decline in language (with language therapy alone or augmented with tDCS). Her research is supported by the National Institute of Deafness and Communication Disorders and by the National Institute of Neurological Diseases and Stroke. She serves as Associate Editor of *Stroke and Aphasiology*, and is on several editorial boards.

ABSTRACT

Background: Stroke is a major cause of disability and death. A significant number of patients with spontaneous intracranial hemorrhage (ICH) die within 30 days. **Objective:** To determine the mortality within 28 days in patients with hemorrhagic stroke.

Materials and methods: This case control hospital based study was carried out in the Department of Medicine of Rangpur Medical College Hospital, from 01 March, 2013 to 31st August 2013. The criterion of diagnosis was the presence of a hematoma in the brain by imaging.

Results: During the study span of 6 months, we studied over 110 patients, with a mean age of 56.02 years at the time of death. Mortality within 28 days was 45.5% (n = 50). Among those victims who died, hospital mortality was in 88% (n = 44) and approximately half of deaths (77.35%, n = 41) occurred within the first 7 days. Mortality was significantly higher among subjects with larger hematomas (>60 cm³) compared to

* Correspondence: Dr Ratindra Nath Mondal. Associate Professor of Medicine, Hypertension and Research center, Rangpur, Rangpur Community Medical College; Rangpur, Bangladesh, Email; dr.ratinmondal@gmail.com.

subjects with smaller hematomas ($<30 \text{ cm}^3$; 68.9% vs. 22.9%, $P = 0.00008$). All stroke patients with ventricular extension, 67.9% ($n = 36$) died within 28 days. In the majority of cases (40.9%), lobar bleeding occurred and mortality was significantly higher in cases of lobar and cerebellar hemorrhage than deep hemorrhage. Glasgow Coma Scale (GCS) and volume of blood together also constituted a good predictor of mortality, as 90.90% (30) of the patients who had $\text{GCS} < 8$ and hemorrhage volume $> 60 \text{ cm}^3$ died within 28 days.

Conclusion: Short-term mortality (28 days) is very high in hemorrhagic stroke. GCS and volume of hematoma were independent predictors of mortality within 28 days.

Keywords: short term, hemorrhagic, mortality, Glasgow Coma Scale (GCS)

INTRODUCTION

Stroke is a major cause of disability and death. Approximately 16 million people worldwide are affected by stroke each year, and the estimated prevalence of stroke survivors is over 60 million [1]. In 2020, stroke will be the leading cause of death and disabilities after cancer throughout the world [2]. Numerous studies have been going on for the past 25-30 years, yet there is no uniform consensus regarding the most important predicting factors of mortality. To reduce the overall burden of stroke in society, an organized approach is needed to predict mortality and morbidity in stroke [3].

Clinicians are often asked to predict outcome after a stroke by the patient, family, nursing staff, therapy team, case managers, and insurance providers. A wide variety of factors influence stroke prognosis, including age, stroke severity, stroke mechanism, location of infarction or hemorrhage, co-morbid conditions, clinical findings, and related complications. However, knowledge of the important factors that affect prognosis is necessary for the clinician to make a reasonable prediction for individual patients, to provide a rational approach to patient management, and to help patient and family understand the course of the disease [4].

Brain imaging is the cornerstone for diagnosis of intracerebral hemorrhage (ICH). Although magnetic resonance imaging (MRI) is an excellent tool for considerable information on the process of acute stroke, MRI is not readily available to most patients who present with acute stroke to a rural or community hospital.

CT scan is the imaging modality of choice in patients presented with acute stroke, which can detect ICH within a few minutes of stroke onset [3]. It is safe and non-invasive and helps to measure the hematoma size, location of the hemorrhage and the presence of intraventricular, subarachnoid or subdural blood, or to find out any mass effect in primary non-traumatic ICH.

All this information is extremely useful in assessing the clinical and functional outcome in acute ICH, which cannot be obtained by clinical examination itself [5].

We have conducted this study to determine the short-term (28 days) mortality outcome of acute hemorrhagic stroke in patients admitted to the Department of Medicine of Rangpur Medical College Hospital.

METHODOLOGY

Populations and Methods

This case control study was carried out at the Department of Medicine, Rangpur Medical College Hospital. During the study span of 6 months, 9000 patients were admitted to the Department of Medicine, of which 902 presented with coma. Common causes of coma included stroke ($n = 4$), encephalitis ($n = 3$), hepatic encephalopathy ($n = 5$), uremic encephalopathy ($n = 4$) and hypoglycemia ($n = 4$), among others.

A convenient sampling method was used to include the study population. Patients presenting with spontaneous ICH were included for this study. The volume of ICH was calculated by the formula $ABC/2$, using the CT slice identified with the largest area of hemorrhage, where A is the largest diameter of the hemorrhage on this slice, B is the largest diameter perpendicular to A on the same slice, and C is the approximate number of 10-mm slices on which the ICH was seen. C was calculated by a comparison of each CT slice with hemorrhage to the CT slice with the largest hemorrhage on that scan. If the hemorrhage area for a particular slice was greater than 75% of the area seen on the slice where the hemorrhage was largest, the slice was considered one hemorrhage slice for determining C ; if the area was approximately 25% to 75% of the area, the slice was considered half a hemorrhage slice; and if the area was less than 25% of the largest hemorrhage, the slice was not considered a hemorrhage slice. These CT hemorrhage slice values were then added to determine the value of C .

All measurements for A and B were made with the use of the centimeter scale on the CT scan to the nearest 0.5 cm. A , B , and C were then multiplied and the product divided by 2, which yielded the volume of hemorrhage in cubic centimeters. The time required for the measurements and calculations was recorded. Hemorrhage volumes determined by this method were found to be in good agreement with measurements made by computer-assisted planimetric image analysis [6].

Procedure of Data Collection

An informed written consent was obtained from each patient or attendant before data collection. Each patient or attendant was interviewed. Besides socio-demographic characteristics GCS (Glasgow coma scale) at the time of admission, after 24 hours and at the time of discharge, blood pressure, neurological deficit, comorbidity, complications such as persistent neurological deficit, bed sores, aspiration pneumonia, urinary tract infection and painful shoulder were recorded. Short-term (28-day) mortality outcome was recorded as obtained by telephone calls to close relatives of the patients.

Procedure of Data Analysis

Data were coded, checked manually and entered into the computer. Data were analyzed using the SPSS-17.0 (Statistical Program for Social Science) software program. Clinical and statistical results are presented in Tables 1-7 and Figure 1.

Table 1. Socio-demographic characteristics of patients (n = 118)

Variables	Frequency	Percentage (%)
Age		
Mean age (SD)	56.02 years (SD $\pm$ 13.45)	
Age range	22-90 years	
Sex		
Male	53	48.2%
Female	57	51.8%
Level of education		
Illiterate	57	51.8%
5 or less class	35	31.8%
>5-10 class	7	6.4%
>10-12 class	2	1.8%
Graduate and above	9	8.2%
Occupation		
Housewife	55	50%
Agriculture	22	20%
Business	13	11.8%
Service	8	7.3%
Retired	4	3.6%
Others	8	7.3%
Monthly income		
<5000 taka*	54	49.1%
5001-10000 taka	27	24.5%
10001-15000 taka	18	16.4%
>15000 taka	11	10%

*1 USD=80 taka.

Of the study participants, 23.6% (26) were current smokers, 10.9% (12) were ex-smokers and 23.6% (26) were sedentary workers. Among the women, 68.42% (39) used different contraceptives (Table 2).

Table 2. Frequency of use of different types of contraceptives (n = 39)

Contraceptive	Frequency	Percentage
Oral	32	56.1%
Injectable contraceptive	2	3.5%
Others (barrier method, biological method)	5	8.8%

Table 3. Co-morbidity of the study population (n = 110)

Co-morbidity	Frequency	Percentage
Hypertension	66	60%
Diabetes mellitus	1	0.9%%
Hypertension and diabetes	3	2.7%
Hypertension, diabetes and dyslipidaemia	1	0.9%
Hypertension and dyslipidaemia	2	1.8%
Hypertension and CKD	3	2.7%
Dyslipidaemia	3	2.7%
Ischaemic heart disease	2	1.8%
No	29	26.2%

Table 4. Site of bleeding among study population

Site of bleeding	Percentage	Mortality at 28 th day
Lobar	40.9% (45)	64.4% (29)
Cerebellum	5.5% (6)	66.7% (4)
Deep hemorrhage (Thalamus and basal ganglia)	39.1% (43)	20.9% (9)
Pons	6.4% (7)	57.1% (4)
Subarachnoid	3.6% (4)	25% (1)
Multiple sites	4.54% (5)	60% (3)

68.18% (75) of the study patients had hypertension and 5.45% (6) had diabetes mellitus (Table 3). A family history of hypertension was present in 55.5% (61) of the patients; among them, hypertension was present in 83.33% (50), and a family history of stroke was present in 24.5% (27). In the majority (40.9%) of cases lobar bleeding occurred and bleeding at multiple sites occurred in 4.54% (5) (Table 4). Different complications following the stroke occurred in 49.1% of the patients. Among the complications, chest infection was the most frequent (29.6%) (Table 5).

Table 5. Complications after intracranial hemorrhage

Complications	Frequency (n = 54)	Percentage
Chest infection	18	33.33%
Bed sore	13	24.07%
Seizure	10	18.51%
Painful shoulder	7	12.96%
Electrolyte imbalance	4	7.40%
Others	2	3.70%

Operational Definitions

Hemorrhagic stroke: Patients presented with sudden onset of focal neurological deficit (e.g., sudden loss of consciousness, aphasia, weakness of one side of the body, sudden loss of vision) and CT/MRI evidence of intracerebral hemorrhage was labeled as hemorrhagic stroke.

Sites of cerebral hemorrhage: The main sites of cerebral hemorrhage are the thalamus, putamen, pons, cerebellum and temporal lobes [7].

Short-term outcome of acute stroke: In our study, the outcome 28 days after onset was taken as short-term outcome (death or survival). Patients alive on day 28 were considered to have survived.

Smoking

Those who currently smoked or had smoked tobacco in any form (cigarette, birri, etc.) in the last 6 months were considered to be smokers. Ex-smokers were patients who gave up smoking at least 6 months before stroke onset.

Smokeless Tobacco (SLT)

SLT consists of raw tobacco leaves not consumed by inhalation (usually taken with betel nut or held between the cheek and jaw).

Statistical Analysis

Socio-demographic data were compared between patients who died and those who survived by one-sample Student 't' test. Their observed differences, expressed as frequency distributions, were tested by the 'chi-square' test. A P-value of <0.05 was considered as statistically significant and 95% confidence intervals were computed.

Ethical Consideration

The ethical committee of Rangpur Medical College approved the study protocol and questionnaire.

RESULTS

During the study span, we examined over 110 patients. The mean age of the patients at the time of death or discharge was 56.02 years. There were slightly more females than males (51.8% vs. 48.2%). The majority of the patients (87.3%) came from rural areas. Table 1 shows the socio-demographic characteristics of the study population.

Mortality within 28 days for patients with intracerebral hemorrhage was 45.5% (50). Among these, hospital mortality occurred in 88% (44). 28-day mortality was slightly higher in females than in males (54% vs. 46%) and the mean age at death was 56.46 years. Most patients who died (62%) were over 50 years of age. Death was more common (65%) in older patients (>70 years), in smokers (57.7%) and in those who had hypertension (54.7%).

Among the ICH patients, volume of blood was >60 cm³ in 40.9%, 30-60 cm³ in 27.3% and <30 cm³ in 31.8%. Mortality was significantly higher in those whose volume of blood was >60 cm³ than those whose volume of blood was <30 cm³ (68.9% vs. 22.9%) (P = 0.0000844) (Table 6).

More than half of the deaths (77.35%; 41) occurred within the first 7 days. 82.35% of the patients who had a volume of blood >60 cm³ died within 7 days, compared with 50% of patients whose blood volume was <30 cm³ (P = 0.00002209). 48.2% (53) of the patients had intracerebral hemorrhage with ventricular extension; 67.9% (36) of them died within the first 28 days and 80.55% (29) of the deaths occurred by the seventh day.

The mean GCS of the study population at the time of admission was 9.06; after 24 hours 9.40 and at the time of discharge 13.27. 88% (44) of the patients who had a GCS of <8 at presentation died within 28 days, and the majority (90.90%) of deaths occurred in the hospital. Only 10% (6) of the patients who had an initial GCS > 8 died within 28 days. A significant improvement of GCS occurred from presentation (GCS = 11.47) to day 28 (14.46) in patients who survived. No significant improvement occurred from presentation (GCS = 6.10) to 24 hours later (6.12) in patients who died (Figure I).

GCS and volume of blood together also constitute a good predictor of mortality within 28 days. The majority (90.90%) of the patients who had GCS<8 and a hemorrhage volume >60cm³ died within 28 days (Table 7).

Among the study population, GCS <8 and ventricular extension were present in 35.46% (39) of patients, and 84.61% (33) of them died within 28 days.

Table 6. Relation of mortality with volume of intracerebral hemorrhage

Volume of blood	Percentage	Mortality at 28 th day
<30 cm ³	31.8% (35)	22.9% (8)
30-60 cm ³	27.3% (30)	36.7% (11)
>60 cm ³	40.9% (45)	68.9% (31)

Table 7. Relation of mortality with GCS and volume of hemorrhage

GCS	Volume of hemorrhage	Percentage/frequency	Mortality
<8	>60cm ³	66% (33)	90.90% (30)
	30-60 cm ³	22% (11)	72.72%% (8)
	<30 cm ³	12% (6)	100% (6)

Figure 1. Time course of GCS in all patients and in patients who died or survived.

DISCUSSION

In the acute phase of stroke, the main predictors of outcome are stroke severity and patient age. Stroke severity is probably the most important factor affecting short- and long-term outcome [8-18]. Intracerebral hemorrhage has a reported 30-day mortality of 42% [19].

Our study found near similar findings at 28-day mortality after spontaneous intracerebral hemorrhage (45.5%). In our study, the majority (77.35%) of deaths occurred by day 7, with more than half of the deaths occurring within 5 days. This finding differs from other studies reporting that more than half of the deaths occurred by the end of the second day [20-21]. Factors independently associated with 30-day mortality were hemorrhage volume, level of consciousness, and presence of intraventricular extension [22].

Different techniques have been developed to measure hemorrhage volume [23-26]. Unfortunately, these methods often involve complicated formulas, require specialized equipment, or cannot be performed rapidly at the patient's bedside.

Broderick [29] showed that the simple formula $ABC/2$ can accurately estimate intraparenchymal hemorrhage volume and requires less than 1 minute for measurement and calculation. The measurements correlate highly with the volumes calculated by planimetric methods for all hemorrhage locations. Rapid calculation of ICH volume at the time of initial patient presentation has clinical utility. For prognosis, a model of 30-day mortality using the Glasgow Coma Scale and hemorrhage volume in patients with ICH correctly predicted outcome with a sensitivity and specificity of 97% [27].

In our study, hemorrhage volume was a strong predictor of short-term mortality. Mortality by day 28 was higher in large hemorrhages ($>60 \text{ cm}^3$) in comparison to small hemorrhages ($<30 \text{ cm}^3$) ($P = 0.0000844$). Large-volume hemorrhage is also a good predictor of mortality within 7 days of onset of intracranial hemorrhage (82.35% vs. 50%) ($P =$

0.00002209). Stroke severity on admission depends on the level of consciousness and was the main clinical predictor of early mortality in many previous studies [28-32]. Level of consciousness can be easily determined at the bedside by the GCS. Our present study showed that GCS at presentation was a good predictor of mortality during the hospital stay and within 28 days. GCS after 24 hours is also a good predictor of improvement or deterioration in ICH patients. GCS and volume of blood together are also a good predictor of mortality within 28 days. Analysis of subgroups showed that 90.90% of the patients with GCS <8 and hemorrhage volume $>60\text{cm}^3$ died within 28 days. But 100% of the patients with GCS <8 and hemorrhage volume $<30\text{cm}^3$ also died within 28 days. Thus, GCS alone is a more reliable predictor of short-term mortality than hemorrhage volume alone. Apart from GCS and volume of hemorrhage, other factors such as site of hemorrhage and complications after stroke may be important determinants of death. In our study, ICH with intraventricular extension was an important predictor of mortality within 28 days ($P = 0.0018$); intraventricular extension along with GCS <8 was also a very important predictor: 84.61% of patients with ICH with intraventricular extension with GCS <8 died within 28 days.

Sukdeb et al. [33] showed that mortality was higher in patients with lobar hemorrhage (40%) than with subcortical hemorrhage (27%); this result is consistent with our findings. In our study, mortality in patients with lobar hemorrhage was 64.4% and in those with deep hemorrhage it was 20.93%. In cerebellar hemorrhage, mortality was found to be 4% [34] and 40% [33] in other studies compared to 66.7% in our study. High mortality may be due to poor resources of surgical evacuation in cerebellar hemorrhage. Advancing age has a major negative impact on stroke morbidity, mortality, and long-term outcome [35-39].

In our study, there was no significant difference of mortality in older (>60 years) or younger (<60 years) patients ($P = 0.57160764$). Data regarding sex differences and stroke outcome are conflicting. In our study, though mortality was slightly higher among females than among males (47.4% vs. 43.4%), the difference was not statistically significant ($P = 0.57160764$).

This study is important because hypertension and stroke in Asia have become highly prevalent, without any strategies for control or prevention [40].

CONCLUSION

Short-term mortality (28 days) is very high in hemorrhagic stroke. ICH with intraventricular extension, GCS and volume of blood independently and together are good predictors of mortality within 28 days.

Limitation

Sample size was small and other factors that may contribute to mortality, such as electrolyte disturbances and infections, were not addressed.

Future Direction

Study with large sample size will be needed to clarify the predictors of mortality in hemorrhagic stroke patients.

Conflict of Interest

There was no conflict of interest.

Chapter 93

ELECTRICAL STIMULATION IN STROKE PATIENTS

Trinidad Sentandreu-Maño*

Department of Physiotherapy,
University of Valencia, Valencia, Spain

ABSTRACT

Surface electrical stimulation is one of the tools suggested for the rehabilitation treatment of patients following a stroke. Although its use is not very widespread in current clinical practice, it is regarded as a non-invasive, low-cost, reliable and easy-to-use treatment which could stimulate recovery in stroke patients. In recent years, the understanding of motor learning, neuronal plasticity and functional recovery after brain damage has improved, and the new findings in neuroscience have given a fresh impetus to research in neurorehabilitation. The number of existing studies regarding electrical stimulation and the stroke patient shows the interest which the subject still provokes and the need to provide more evidence that will assure its beneficial effect in clinical practice. Current lines of investigation are principally focussed on the recovery of the upper-limb, lower-limb and gait, hemiplegic shoulder, dysphagia, urinary incontinence and visuo-spatial neglect. Additionally, different modalities of application are presented and the most effective protocols are investigated, including their complementary use with other therapeutic strategies and new technologies. In this chapter, these points are extensively discussed to showcase the latest evidence, shed more light on this intervention in the field of neurological rehabilitation and establish future lines of interest in which advances in neuroscience and technological development play a significant role.

Keywords: surface electrical stimulation, stroke, neurorehabilitation

INTRODUCTION

Neuromuscular electrical stimulation (NMES) involves the use of electrical current to stimulate neural and muscular structures (Rodríguez, 2004). Although NMES can be applied

* Corresponding Author's Email: trinidad.sentandreu@uv.es.

using superficial, percutaneous or implanted electrodes (IJzerman et al., 2009), in this chapter we will further explore the superficial electrical stimulation as a therapeutic strategy, presented as a non-invasive (Díaz et al., 2005), low-cost, reliable and easy-to-use treatment (Glanz et al., 1996; Sentandreu et al., 2011). NMES has been applied for different purposes and in different pathologies. Among such pathologies, it has been suggested for the treatment of patients following a stroke (Howlett et al., 2015).

A stroke is a sudden, non-convulsive loss of neurological function due to an ischemic or haemorrhagic intracranial vascular event (Mehrholtz et al., 2013). It is the main cause of adult disability and the third most common cause of death in Europe (Scutt et al., 2015). The incidence of stroke increases with age (Rigau et al., 2009) and due to the progressive aging of the population more health care requirements are expected in the case of these patients (Bermejo et al., 2009). In addition to disturbances in the cognitive and affective domains, the loss of motor function represents the most serious condition after a stroke (Soekadar et al., 2015). In this respect, the rehabilitation of patients after a stroke constitutes a worldwide challenge (Liu et al., 2016) and innovative methodologies for the purpose of restorative neurorehabilitation are urgently required in order to reduce long-term disability (Dutta et al., 2014).

The first paper reporting on the use of NMES in neurological patients was published in 1961. Liberson et al. (1961) described the use of electrical current to stimulate the dorsal flexors of the foot in stroke patients to prevent drop-foot during the swing phase of gait. Since then, the understanding of motor learning, neuronal plasticity and functional recovery following brain damage has improved and the new findings in neuroscience have given a new impetus to research in neurorehabilitation. This improved understanding has led to the identification of new clinical roles, challenges and emerging research in the field of NMES and stroke patients.

The vast number of existing studies concerning this subject is indicative of an ongoing interest and an increasing need to provide further evidence that will ensure the beneficial effect thereof in clinical practice. Current lines of investigation are principally focussed on the recovery of the upper-limb, lower-limb and gait, hemiplegic shoulder, dysphagia, urinary incontinence and visuo-spatial neglect; different modalities of application are presented and the most effective protocols are investigated, including their complementary use with other therapeutic strategies and new technologies. These points are discussed in greater detail within the framework of this chapter to show the most recent evidence, shed more light on this intervention in the field of neurological rehabilitation and set out future lines of interest in which advances in neuroscience and technological development play a significant role.

UPPER-LIMB

Impairment of the upper limb is one of the most frequent consequences of stroke (Mangold et al., 2009) and directly impacts on the patient's function and quality of life. It is estimated that less than 50% of stroke survivors will recover arm function (Nakayama et al., 1994), which will exert a great economic, social and personal toll. Among the different therapeutic tools, NMES has been proposed in several studies as a strategy in the rehabilitation of the upper limb of stroke patients, and different reviews and meta-analyses

support its use (Howlett et al., 2015; Nascimento et al., 2014). However, despite of it, this topic remains at present a research focus for various authors as can be seen with the number of studies in the literature.

The most recent research on electrical stimulation and upper limb recovery focuses mainly on the most effective protocols by comparing different variables of the applied programmes (i.e., NMES modalities, stimulation parameters, electrode placement, etc.), the characteristics of the patients who can benefit most from this treatment, its effectiveness as a complement to other emerging therapies, and its effects not only locally but also its impact on the central nervous system.

Regarding the main NMES modalities found in the randomised controlled trials (RCTs) reviewed, certain studies have applied sensory or motor electrical stimulation thresholds. In the first approach, the stimulation evokes a sensory reaction without muscle contraction. Some authors also include the transcutaneous electrical nerve stimulation (TENS) modality in this group. In the second approach, where a muscular contraction is provoked, several applications can be distinguished: cyclic NMES (without voluntary activity by the patient), sensor or electromyographic (EMG)-triggered NMES (activated voluntarily by the patient) and functional electrical stimulation (FES) (associated with the performance of functional tasks). In some of these cases, NMES treatment was applied by orthosis. One of the most used models in the studies reviewed is the NESS H200 surface FES system for upper limbs (Bioness Inc., Santa Clarita, CA, USA). This model combines wrist-hand orthosis with muscle activation of the paralyzed forearm and hand via integrated surface electrodes. It allows consistent replication of the grasp, hold and release functions of the hand.

Few previous studies have directly compared electrical stimulation modalities, and although many modalities have been established, conclusive proof of their effects is still lacking (Hara et al., 2008). De Kroon et al. (2008) and Boyaci et al. (2013) compared cyclic NMES and EMG-triggered NMES, and found no difference in outcomes. These findings disagree with the review by Kroon et al. (2005), which argued that electrical stimulation triggered by voluntary movement appeared to be more beneficial than other NMES modes. It has been hypothesized that the intention to execute a movement, along with peripheral activity, reinforces plastic changes further compared to cyclic stimulation (Quandt and Hummel, 2014). A recently published study (Wilson et al., 2016) that compared the effect of cyclic NMES, EMG-triggered NMES and sensory stimulation, concluded that all groups exhibited significant improvement of impairment and functional limitation in the upper limb, though there was no difference based on the type of electrical stimulation administered.

Electrogoniometers, bend sensors, touch sensitive mats, and accelerometers are among the external sensors that have been incorporated into NMES systems (Knutson et al., 2015). Researchers also continue to explore the use of signal collection from the impaired upper limb to not merely trigger the onset of a preset intensity and duration of stimulation but also to control the intensity and timing of stimulation. A challenge for EMG-triggered NMES modalities is that the effort required from patients to contract the muscle does not develop flexor synergies or hypertonia (Knutson et al., 2015).

Contralaterally controlled functional electrical stimulation (CCFES) is an innovative method of sensor-controlled stimulation that uses movement from the unimpaired side to control the timing and intensity of stimulation to the paretic side. The hand system consists of a glove with bend sensors worn on the non-paretic hand and a multi-channel stimulator that delivers stimulation to the paretic hand extensors with an intensity that is proportional to the

degree of opening of the glove. A recent study indicated that CCFES improved hand dexterity more than cyclic NMES in chronic stroke patients (Knutson et al., 2016).

Recent advances in neurotechnology have led to the development of brain-computer interfaces (BCIs) that translate brain activity into control signals of computers (Venkatakrisnan et al., 2014). This technology provides a means to decode mental states and activate devices according to user intentions, and could provide a direct feedback on the engagement of motor areas of the brain surrounding the lesion site (Millán et al., 2010). BCI combined with output devices such as FES has also been studied (Silvani et al., 2011). BCI with a FES system has been explored as a potential rehabilitation tool for motor learning after stroke because FES can assist such patients in learning and practicing the desired coordinated movements (Müller-Putz et al., 2005). Biasiucci et al. (2013) reported preliminary results of a BCI with a FES system for stroke rehabilitation where the user's intention to perform an extension movement of the affected hand was detected through a BCI and used to activate a FES device. These results confirmed the beneficial effects of direct muscle stimulation according to user intentions to perform a motor task. Along the same line, Daly et al. (2009) carried out a case study which demonstrated the feasibility of combining BCI and FES for motor learning in stroke patients. After training sessions, volitional control of isolated finger extension was obtained. These results showed that combining BCI and FES promoted motor recovery. The authors argued that this improvement could be attributed to BCI, FES, specific target-oriented physical practice or a combination thereof. In this way, RCTs are required to determine whether BCI actually can have an additive effect beyond FES alone and to recognise the characteristics of stroke patients who can successfully use BCI as a motor learning paradigm. On the other hand, Kim et al. (2016) investigated the effects of action observational training (AOT) plus BCI-based FES on improving upper arm function in stroke patients. Their findings suggest that AOT plus BCI-based FES has a positive influence on upper extremity performance by improving functional mobility and ROM of paretic stroke patients.

Specific stimulation parameters are the subject of debate (Quandt and Hummel, 2014). As is also pointed out in other reviews, the comparison of stimulation parameters is complicated due to the disparity of variables or the omission of data. It has been mentioned that neurophysiological responses vary according to the parameters used, and though their clinical relevance has not been verified, even they may not be crucial in determining the effect of electrical stimulation (de Kroon et al., 2005). The most commonly used were low frequency rectangular biphasic currents, with frequency values of 20 and 100 Hz. The intensity was adapted to the sensory or motor threshold, the pulse duration varied between 100 and 500 μ s, and duty cycles as well as ramping up/down periods presented different combinations, in addition to treatment doses. Cauraugh et al. (2003) compared protocols with different times of contraction, concluding that better results were obtained with stimuli of 10 s. Doucet and Griffin (2013) compared protocols with different frequencies and concluded that the effects differ depending on the frequency applied. Sentandreu et al. are currently finalizing a study where two experimental groups with different stimulus frequencies and a control group with conventional therapy have been compared. Their results will be published soon. Clair-Augier et al. (2012) investigated the effect of pulse duration on the paretic and non-paretic arm and found a significant increase in elbow flexion torque for the former when using a wide-pulse stimulation scheme (1 ms). It was speculated that wide-pulse stimulation may lead to a greater reflexive recruitment in the paretic arm, highlighting that pathological

changes influence stimulation response. Conforto et al. (2010) concluded that sessions of repetitive peripheral nerve sensory stimulation (PSS) could facilitate motor function after subacute stroke depending on the intensity of the stimulation used. The authors proposed that careful dose-response studies are needed to optimise parameters of PSS before designing costly, larger, double-blind, multi-centre clinical trials.

Regarding treatment doses, in the meta-analysis of Pomeroy et al. (2006), it was pointed out that the length of time that NMES is applied could influence its effectiveness. Some studies have also remarked that one of the reasons for the lack of effectiveness of some programmes could be due to the short duration of treatment (Rosewilliam et al., 2012; Popovic et al., 2002), as well as the need for longer protocols in patients with severe impairments (Mangold et al., 2009; Alon et al., 2008; Popovic et al., 2003). Page et al. (2012) compared the efficacy of different rehabilitation protocols in subacute stroke patients and found that 120 minutes of repetitive task-specific practice combined with electrical stimulation was superior compared to shorter durations of stimulation. In contrast, Hsu et al. (2010) argued that higher and lower doses of NMES led to similar improvements in motor function. A minimum of 10 hours of NMES in combination with regular rehabilitation may improve recovery of arm function in acute stroke patients with severe motor deficit. Along the same line, Kowalczewski et al. (2007) compared two protocols of high and low intensity and only some measures obtained significant changes. Lourenção et al. (2005) reported that six months of FES were necessary for a significant improvement in grip speed, and it was hypothesized that five months would be necessary for an effective programme to improve upper limb function.

As for the electrode placement and stimulated musculature, there is also a diversity of options. Some studies have applied NMES at a unique segmental level in agonist and/or antagonist musculature, and others have made a multi-segmental application, applying electrical stimulation in several segments of the upper limb. There is evidence that greater effect sizes are associated with movements that stimulate functionally useful movements, as seen in studies that stimulate more than one joint (Farmer et al., 2014) such as that by Meadmore et al. (2014). They applied FES to three muscle groups in the upper limb and completed coordinated, repetitive, goal-oriented movements using real objects, controlling the FES signal to each muscle using advanced iterative learning control algorithms in order to ensure that the resulting movement precisely coincided with unimpaired task competition. The positive results indicated that multiple muscle stimulation along with the application of iterative learning technology is promising in stroke rehabilitation and may prove effective in reducing upper limb impairments. De Kroon et al. (2004) compared the stimulation of extensors and flexor-extensors and found no difference. Hara et al. (2007) argued that the combined use of distal EMG-NMES and proximal stimulation (anterior deltoid and triceps brachii) could be more efficient on a functional level.

Concerning patient characteristics, some studies have pointed out the importance of suitable sample selection (Powell et al., 1999; Sentandreu et al., 2011). It has also been claimed that motivated patients (Kroon et al., 2005) with moderate impairment (Powell et al., 1999) and residual motor function (Popovic et al., 2003; Powell et al., 1999) could benefit from NMES. According to this, Chae et al. (2008) added that mild to moderately impaired subjects could benefit most.

Recent studies have investigated NMES combined with other emerging physical therapy approaches and new technologies such as mirror therapy, mental imagery training, bilateral

movement training, constraint-induced movement therapy (Page et al., 2006) and robotics. Superior effects were shown in studies employing protocols where electrical stimulation was combined with the mirror therapy (Kim et al., 2015; Lin et al., 2014; Yun et al., 2011). Hong et al. (2012) combined EMG-triggered FES with mental imagery training and observed an advantage over FES alone. In contrast, Hemmen et al. (2007) investigated the effect of movement imagery combined with EMG-triggered NMES compared with a conventional NMES programme and concluded that there was no difference between the two therapeutic protocols. With regard to bilateral movement training, on the one hand, Cauraugh et al. (2002, 2005) concluded that the results were more prevalent in groups where EMG-triggered NMES was applied along with bilateral movement training. Knutson et al. (2007) as we have described before, also obtained more benefits in CCFES compared with cyclic NMES. This modality also combines the effects of NMES, active and goal-oriented training, and bimanual symmetric exercises involving the unaffected upper limb in the training of the affected upper limb. On the other hand, Singer et al. (2013) did not show that a protocol applying bilateral tasks plus EMG-triggered NMES was superior to the unilateral equivalent.

With regard to robotic systems, there is a paucity of information regarding the comparative benefit of NMES (McCabe et al., 2015). O'Connor et al. (2015) investigated the feasibility of using the iPAM Mk2 dual robot rehabilitation system with NMES to provide simultaneous hand opening exercises during assisted reaching exercises for stroke survivors who have moderate to severe arm impairment. Based on the promising findings in this report, the authors suggested that future work be planned to explore the possibilities of further combinations, including in lower limb rehabilitation, and to optimise the characteristics of robotic and stimulation parameters. Hu et al. (2015) concluded that NMES robot-assisted wrist training was more effective than the pure robot training. The additional NMES application in the treatment could result in more improvements in distal motor functions and faster rehabilitation progress. McCabe et al. (2015) compared the response to upper-limb treatment using robotics plus motor learning (ML), FES plus ML and ML alone, in a group of chronic severely impaired stroke survivors. The authors did not find any difference in treatment response across the three intervention groups according to the measures of joint movement coordination or complex functional task performance. On the other hand, Daly et al. (2005) pointed out that comparison of NMES and robotics resulted in different outcomes depending on the therapy applied.

Despite the increased knowledge regarding neural plasticity and brain mapping studies, the specific mechanisms of action of these different electrical stimulation modalities are not clear. It has been speculated that therapeutic effects are probably caused by a combination of local and central effects. At the local level, reference has been made to changes in muscular strength, modification of viscoelastic characteristics and increase of blood flow, among others (de Kroon et al., 2004; Ring et al., 2005). Quandt and Hummel (2014) argued that NMES could influence cortical reorganization. It is hypothesized that either concurrent stimulation of afferent fibres, or antidromic stimulation lead to enhanced synaptic remodelling, but evidence is still lacking. Hara et al. (2008) suggested that sensory components of large afferent fibre activation, proprioceptive input, and increased cognitive sensory attention could enhance voluntary movement and function. NMES is associated with concomitant physiologic changes in the brain including activation of primary sensory and motor areas and the supplementary motor area, reduction of intracortical inhibition, and increased amplitude of motor-evoked potentials (Chae et al., 2008). Currently, with access to advanced neuroimaging

tests, many studies are aimed at investigating the changes that NMES causes at the level of the central nervous system. Several studies demonstrated evidence of central mechanisms using neurophysiologic experiments such as reaction time and fMRI (Chae et al., 2008). Kimberley et al. (2004) indicated that the NMES programme resulted in improvements in the functionality of the hand and these were associated with an increase in cortical intensity in the ipsilateral primary sensory cortex. According to these authors, Quandt and Hummel (2014) argued that most of the reviewed studies found changes of neural activation after NMES use and a trend towards severe impairment leading to activation of the contralesional sensorimotor cortex can be observed. On the other hand, less impaired patients tend to recruit the ipsilesional site. The literature of cortical reorganization during stroke recovery, describing the relationship of lateralization and functional outcome, supports these conclusions.

LOWER-LIMB AND GAIT

Post-stroke gait dysfunction is among the most investigated neurological gait disorders and one of the principal goals of post-stroke rehabilitation (Lindquist et al., 2007). At the level of the lower limb, paresis, along with the inability to grade muscle contractions, poor motor coordination, poor endurance, spasticity, and impaired balance have significant consequences on ambulation (Eng et al., 2007). In particular, the inability to dorsiflex the ankle during the swing phase of gait affects approximately 30% of patients following a stroke, which increases the risk of falls and mortality (Bosch et al., 2014). These impairments have an important impact in patient's life and entail considerable costs for health and social services (Evers et al., 2004).

With reference to the electrical stimulation modalities, NMES to the lower extremities is mainly used by post-stroke patients as an alternative to mechanical orthotic devices during gait or as a training modality during rehabilitation (Kafri et al., 2015). In the second approach, the same modalities described in the upper limb may be observed. Nevertheless, the most widely used alternative is FES, which is associated with the performance of functional activities.

In 1961, Liberson et al. (1961) used FES as a substitute for traditional drop-foot correction within a hemiplegic population. By triggering a foot switch, a single-channel electrical stimulation device stimulated the common fibular nerve via a surface electrode, resulting in dorsiflexion during the swing phase of gait. This led to the first commercially available surface electrode stimulator. Since then, advances in technology and the development of wireless FES systems for the purpose of drop-foot correction have become commercially available and are used as an alternative to the ankle-foot orthosis (AFO) (Kafri et al., 2015). A trigger is used to stimulate the muscles during the specific phases of gait. The most common trigger is a foot switch, which is activated by the user's weight upon initial contact. The dorsiflexion can also be stimulated via the use of a tibial tilt sensor capable of detecting the tibial position during the terminal stance (Bosch et al., 2014). Recently, several devices have been commercially introduced for drop-foot correction. Relevant examples within this context would be the WalkAid® (Hanger Orthopaedic group), a surface peroneal nerve stimulator controlled by a tilt sensor attached just below the knee; the NESS L300™, a

new-generation surface electrical stimulation system for drop-foot controlled by a heel switch that wirelessly communicates with the stimulator integrated within a semi-rigid orthosis positioned just below the knee; and the Odstock Dropped Foot Stimulator, which represents one of the most widely used and best documented surface stimulation systems. A portable gait event detection device is essential for ensuring the appropriate timing of the stimulation. A variety of sensors, such as goniometers, gyroscopes, accelerometers, inclinometers or force sensitive resistors and various sensor combinations have been developed in order to meet these requirements (Kafri et al., 2015).

As was described in the upper limb section, CCFES has also been used to improve recovery of ankle dorsiflexion in chronic and subacute stroke patients. Initial studies provided preliminary evidence in support of the efficacy thereof (Knutson et al., 2012).

There has been a growing interest in employing BCI technology in combination with FES in post-stroke gait therapy (McCrimmon et al., 2015). Chung et al. (2015) conducted a pilot study in order to determine the BCI-FES effects on balance and gait function in patients with stroke. The results of this study suggested that BCI-FES training constituted a more effective exercise for the amelioration of balance and gait function as opposed to FES training alone in patients with stroke. The authors argued that further studies are needed to investigate its long-term intervention effects. In addition, McCrimmon et al. (2015) explored the safety and feasibility of a foot-drop-targeted BCI-FES physiotherapy in chronic stroke survivors. The authors concluded that BCI-FES therapy was safe and that a large number of subjects experienced improvements in terms of gait speed and dorsiflexion aROM.

Optimal treatment protocols for the lower limb and gait recovery are difficult to elicit due to the inconsistent and wide ranging outcome measures, varying modalities to NMES, and the different stimulation parameters used (Kafri et al., 2015). Kafri et al. (2015) reported that in the case of reviewed studies, frequency values generally ranged between 15-50 Hz, whereas pulse duration varied between 280-400 μ s in line with a current amplitude value of 4-85 mA. The authors indicated that the stimulation parameters were not reported in a consistent manner, stating that while some studies did not report any parameters, others varied in the amount of detail provided. Kesar et al. (2010) compared knee and ankle kinematics during the swing phase of gait when FES was delivered to the ankle dorsiflexors using variable frequency trains (VFTs) versus constant-frequency trains (CFTs). A 30 Hz constant-frequency train was applied in the case of FES using CFTs, whereas a 3-pulse burst of high frequency (200 Hz) followed by a lower frequency (30 Hz) was applied in the case of FES using VFTs. The authors concluded that novel FES systems capable of delivering VFTs during gait can result in an enhanced drop-foot correction as opposed to the traditional FES systems that deliver CFTs. The results also suggested that the delivery timing of FES during gait was critical and that it is also required further investigation. Concerning doses, Smith et al. (2003) have demonstrated a dose-response relationship between FES and brain activation in sensory and motor regions contralateral to the stimulation and it is also suggested that more intensive training may be beneficial (Bosch et al., 2014). In relation to the electrical stimulation orthotic substitute devices, Bosch et al. (2014) pointed out that the limited total intervention time, small sample size, and lack of focus on gait training raise questions about the optimal interventions and training intensity needed to obtain beneficial effects.

There is evidence supporting the use of electrical stimulation for therapeutic training and as a replacement or alternative to an AFO (Bosch et al., 2014). These positive effects may include changes in gait characteristics and body function variables (Kafri et al., 2015). The

therapeutic effect of FES on balance did not demonstrate any clear patterns. In addition, consistent findings indicate that when FES is used as an alternative to an assistive device it has no superior therapeutic effects than AFO (Kafri et al., 2015; Bosch et al., 2014).

In terms of patient characteristics, it is not clear which individuals will benefit most from NMES, and what baseline characteristics predict better therapeutic outcomes (Kafri et al., 2015). Merletti et al. (1979) suggested that the time since lesion, spasticity, and intensity of treatment are important predictors of positive therapeutic results.

The use of FES combined with different walking strategies has been shown to result in improvements in hemiplegic gait (Belda-Lois et al., 2011). These methods include cycling, leg movements in a side lying position, treadmill training, electromechanical gait training and so on. FES has also been applied in conjunction with mirror therapy indicating good results in gait ability, muscle strength and balance in hemiplegic stroke survivors (Ji et al., 2014; Lee et al., 2016). Preliminary studies have been carried out in relation to a multi-level NMES paradigm with a virtual reality-based adaptive response technology for post-stroke balance rehabilitation (Dutta et al., 2014). NMES can also be used along or as a part of a neuro-robot (Moreno et al., 2011), yet this evidence is still limited. Future research topics have been suggested in relation to the combination of FES and Lokomat-assisted robotic rehabilitation therapy that might lead to further mobility improvements (Jezernik et al., 2003).

Locomotion results from intricate dynamic interactions between a central programme and feedback mechanisms (Belda-Lois et al., 2011). While functional changes in mobility performance may be attributed to the direct effects on muscle structure and function, two other central mechanisms may be involved namely the direct effects of electrical stimulation on brain plasticity and the enhanced motor learning resulting from repetitive practice (Kafri et al., 2015). Findings indicate that NMES in conjunction with voluntary muscle contractions is superior to individual NMES in terms of cortical excitability and plasticity (Kafri et al., 2015).

HEMIPLEGIC SHOULDER

The hemiplegic shoulder constitutes a challenge in the rehabilitation of stroke patients. Shoulder subluxation may affect the upper limb treatment process. It can also lead to additional complications, such as pain and delays in functional recovery (Vafadar et al., 2015; Gu et al., 2016).

Various meta-analyses and reviews have been published on this subject in recent years. Sheffler et al. (2007) argued that the use of NMES appears to reduce shoulder subluxation along with the pain-free ROM, as well as facilitate motor recovery, especially in the case of acute stroke patients. However, additional studies are required in order to clarify the clinical efficacy thereof. The conclusions formulated by Vafadar et al. (2015) and Gu et al. (2016) indicated similar findings. Both authors pointed out that NMES could be used in order to prevent or reduce shoulder subluxation early after a stroke, yet findings did not support their efficacy for pain reduction, improvement in arm strength, movement, functional activity, and quality of life following a stroke.

The NMES protocols applied to the hemiplegic shoulder are very disparate and clinical trials do not fully describe them in the majority of cases, thus making it difficult for a

comparison to be made between the studies. The stimulated musculature, which includes the supraspinatus and the posterior deltoid, is the only variable that most studies have in common, whereas the rest of the stimulation parameters vary from one author to another. The frequency ranges mainly between 10 and 30 Hz, the most frequent pulse duration is 300 μ s, although on many occasions these values are not defined by the author. The waveform as along with the intensity parameters also fail to be indicated in the vast majority of studies. Furthermore, ramping up/down periods and duty cycles are very different in the defined protocols, which is also the case for the treatment doses.

More extensive and accurate studies should be carried out in order to reach conclusive results about the long-term effects of NMES and their relation to the post-stroke time period (Vafadar et al., 2015; Gu et al., 2016).

DYSPHAGIA

Dysphagia or swallowing problems are common and they occur in 45-65% of patients following an acute stroke (Daniels et al., 1998; Lee et al., 2014). Complications of dysphagia include aspiration leading to chest infections and pneumonia, malnutrition, inability to rehabilitate, prolonged length of hospitalisation, and an increased risk of death (Geeganage et al., 2012). Different interventions are applied in order to accelerate the recovery of the swallowing function. NMES for the treatment of dysphagia is a relatively new therapeutic method (Poorjavad et al., 2014; Tan et al., 2013; Park et al., 2012). This new approach has generated a lot of interest across a vast amount of publications in recent years, yet the available evidence is limited (Chen et al., 2016; Poorjavad et al., 2014).

A recent meta-analysis (Tan et al., 2013) evaluated the effect of NMES versus traditional therapy (TT) in patients with dysphagia of different aetiology. In the subgroup analysis of stroke patients, the effectiveness of NMES and TT was comparable, patients with dysphagia may benefit to a greater extent from NMES when combined with TT. Following the same approach, the latest meta-analysis (Chen et al., 2016) concluded that swallowing treatment by means of NMES seems to be more effective than the interventions without it in the case of post-stroke dysphagia in the short term, and the authors remarked that the evidence is insufficient in order to indicate whether NMES alone is superior to swallowing therapy.

Related to the NMES protocol, after reviewing various clinical trials, the device predominantly used is the Vitalstim® equipment (Chattanooga Group, Hixson, TN, USA, device approved by the FDA for the treatment of dysphagia), including biphasic pulses, a frequency of 80 Hz and a pulse duration of 700 μ s. The stimulation intensity is adjusted according to the motor or sensory threshold, the usual dosage of treatment is 60 min per day for 5 days per week, with the duration of the study fluctuating between 5 days and 6 weeks. On the same subject, a review (Poorjavad et al., 2014) related to the dysphagic patients following a stroke, analysed the intensity of stimulation (sensory or motor level) and the electrode placement at the level of the neck in more detail. The authors pointed out that these two parameters of the protocol could have important effects on the outcomes and they had not been extensively considered by previously published reviews (Steele et al., 2007; Clark et al., 2009; Tan et al., 2013). Generally, NMES on the swallowing muscles has been applied with two general purposes, namely to cause muscle contractions in which case the intensity of the

electrical current is increased until the muscle contraction occurs, and to stimulate the sensory pathways in which case the sensory threshold is usually identified as the lowest current level at which the patient feels a tingling sensation in the neck skin. Electrode placement usually involves the suprahyoid or infrahyoid muscles. According to this review, the majority of the studies reported some positive treatment outcomes in the case of the electrical stimulation to the neck musculature in relation to the swallowing function of stroke patients, especially when the intensity of the stimulus was adjusted at the sensory level or when the motor electrical stimulation was applied to the infrahyoid muscles when swallowing. Nevertheless, additional studies ought to be carried out in relation to the physiologic and neurologic effects of these therapeutic methods, which would help to design specific and individual treatment protocols. Rofes et al. (2013) compared the efficacy and safety of 10 days of treatment with NMES being recorded at sensory and motor intensities in chronic post-stroke patients. The authors concluded that NMES improved the swallow response and safety of swallow both at sensory and motor intensities, and the efficacy of swallow following the motor treatment. A more significant effect was observed when the stimulus was applied at motor intensities.

The mechanisms underlying the efficacy of electrical stimulation in the treatment of post-stroke dysphagia are not well-known. Gallas et al. (2010) reported that the plasticity of the sensory swallowing cortex is presumed to be based on the long-term reorganisation of the human cortex driven by the sensory stimulation. Rofes et al. (2013) and Chen et al. (2016) suggested that both peripheral and central modifications could be responsible for the effect of the therapy, whereas Sun et al. (2013) mentioned that NMES could improve the hyolaryngeal elevation, restore motor function of weak muscles, combat disuse atrophy, enhance sensory awareness and facilitate muscle contractions.

URINARY INCONTINENCE

Urinary incontinence (UI) following a stroke affects more than one-third of acute stroke patients (Liu et al., 2016), namely between 40% and 60% of patients who are hospitalised, 25% of patients upon hospital discharge, and 15% of patients one year after stroke (Thomas et al., 2011). NMES has also been proposed as a treatment tool for the patients with post-stroke urinary symptoms (Skeil et al., 2001; Cooperberg et al., 2005), although there is a paucity of existing research about it. The rehabilitation of patients with post-stroke UI is still a relatively new topic, and its occurrence has not been identified as a problem by therapists, even in developed countries (Guo et al., 2014).

Guo et al. (2014) investigated the therapeutic effect of TENS on post-stroke UI. The treatment group received therapy by means of TENS for 30 minutes once a day over the course of 60 days, at a pulse duration of 70 μ s and a frequency of 75 Hz. In terms of the electrode placement, the positive electrode was placed on the second lumbar spinous process, whereas the two negative electrodes were located on the inside of the middle and the lower third of the junction between the posterior superior iliac spine and the ischia node. The daily micturition, nocturia, urgent urination, and urge UI in the treatment group improved significantly compared to the control group. Later, the same authors published another related article (Liu et al., 2016), comparing two protocols in which TENS was applied at different frequencies, namely 20 Hz and 75 Hz, and pulse durations of 150 μ s, for 30 min once per day

over the course of 90 days. This time, two positive electrodes were used, which were placed in the region of the second sacral level on opposite sides of the vertebral column, whereas the negative electrodes were placed in the same manner as the previously published article. The stroke patients treated with a frequency of 20 Hz had superior Overactive Bladder Symptom Scores, Barthel Index totals, urodynamic values and voiding diary parameters. Despite obtaining promising results, the authors recommend that more studies involving larger sample sizes and longer follow-up periods ought to be conducted in order to confirm the long-term effects of electrical stimulation.

VISUO-SPATIAL NEGLECT

Visuo-spatial neglect is a neurological disorder that often follows a stroke, especially after sustaining damage to the right hemisphere of the brain. It refers to the defective ability of patients to explore the side of the space contralateral to the brain lesion and to report stimuli presented in that portion of the space (Vallar et al., 1998). Different types of interventions are suggested. Electrical stimulation is investigated in some studies, although the use thereof is not very widespread and well-known.

There are few clinical trials in the case of this specific population. Many of these investigations include samples with other neurological disorders that also sustain brain lesions. Vallar et al. (1995) reported that TENS applied to the muscles on the left side of the neck led to a temporary improvement in 93% of neglect patients due to different neurological disorders. Left-hand stimulation had a comparable effect. Schröder et al. (2008) recommend TENS as a possible visual neglect therapy based on the results of their research. They compared different treatments, namely exploration training alone and in combination with TENS or optokinetic stimulation (OKS). In the case of TENS group, the stimulation frequency was set at 100 Hz with a pulse duration of 100 μ s (as in the study of Vallar et al., 1995). The positive electrode was placed over the left trapezius muscle halfway between the head and the shoulder and the negative one was attached about 40 mm below, on the upper left shoulder. The intensity was individually determined by increasing it gradually until a pleasant tingling in the neck was reported. Each patient received 20 therapy sessions each lasting between 25 and 40 min over a period of 4 weeks. The results of this RCT indicated that the groups receiving TENS or OKS showed significant improvements in their reading and writing abilities, although the improvement in neglect test scores disappeared during the follow-up period in TENS group. Pérennou et al. (2001) demonstrated the manner in which it is possible to modulate the postural instability in neglect patients by means of an appropriate somatosensory manipulation, namely the use of TENS. The authors concluded that TENS stimulation applied at the neck level could be a convenient tool for inducing postural neuromodulation in a clinical context. However, the duration of the TENS efficiency with reference to the postural stability lasted for a short period of time. In this regard, further investigation is needed to determine whether repeated applications of TENS eventually associated with some active retraining techniques will facilitate the functional restoration of neglect patients after a stroke.

The specific mechanisms underlying this intervention are complex and unclear, but the latter findings suggest that TENS may elicit a proprioceptive input through large diameter

afferents (Vallar et al., 1995). Vallar et al. (1995) suggested that the improvement could be attributed to a resulted from a non-specific activation of the right hemisphere or a directional effect on the egocentric coordinates of the extrapersonal space. The activation of the neural systems involved in the organization of the egocentric representation has also been suggested by Schröder et al. (2008) and Pizzamiglio et al. (1996). Lomber and Payne (1996) regarded the unilateral neglect as the result of an imbalance in the activity of the two hemispheres at the cortical or subcortical level. In this manner, TENS might serve to reduce this imbalance by increasing the activity of the right hemisphere.

CONCLUSION

Advances in neuroscience and the development of new technologies will possibly give rise to new applications of NMES for upper limb recovery after a stroke. Future NMES protocols should take into account various aspects including bilateral activity, repetitive movement, maximum subject attentiveness, and tasks that motivate goal-driven motor skills. These variables are suspected to promote motor relearning and to enhance the recovery of upper limb in stroke patients. NMES could be a complement to rehabilitation programmes along with other emerging therapies. Further research is needed to establish whether the parameters, treatment doses and patient characteristics are crucial for the effectiveness thereof. Such research should also elucidate the specific mechanism of action associated to the different stimulation modalities in order to select the most suitable patients and to optimise individual treatment protocols to achieve larger treatment effects.

Further research is also required in order to investigate the neurobiological principles that underlie any functional changes in lower limb and gait, to elicit the subpopulation of stroke patients that will most benefit therefrom and to evaluate their effectiveness in line with other emerging strategies. These studies would also be useful in order to optimise the protocols applied. Lower limb and gait programmes should include training principles such as goal-directed, task-specific training, intensive in terms of the number of repetitions, challenging, and motivating, in an attempt to facilitate motor learning on the basis of neural plasticity. In addition, further technological advances are expected to increase the availability and usability of gait FES systems, while in turn significantly contributing to gait and quality of life of post-stroke patients. These new systems should be associated with cost effectiveness studies in order to assess its viability in clinical practice.

In relation to the hemiplegic shoulder, It would be interesting to carry out RCTs with the aim of comparing different treatment protocols in order to determine which parameters are the most effective, as well as to consider whether the treatment programme could be different depending on the patient characteristics. An accurate assessment of the shoulder to be treated and a more homogeneous selection of the sample could provide more information about the effectiveness of NMES on the hemiplegic shoulder and establish protocols in accordance with the treatment purpose.

With reference to the future lines of research in relation to post-stroke dysphagia, there is a need to carry out future controlled studies with larger group of patients and a long-term follow-up period. New findings could thus be used in order to optimise the electrical stimulation parameters, to investigate the role of lesion sites and time from stroke, and to

study the neurophysiologic measurements of cortical excitability with the purpose of confirming the action mechanism of the therapy.

Future research is needed to obtain more concluding results in the case of novel strategies associated to urinary incontinence and visuo-spatial neglect in order to establish effective treatments.

It is therefore important to possess extensive knowledge about the effects of NMES in these different areas and to further investigate their maintenance during the follow-up period, in order to guide clinical decisions and the bioengineering community in the development of appropriate technologies. New advances in nanotechnology, e-textiles and telerehabilitation will play an interesting role in future stroke rehabilitation. A combination of different rehabilitation strategies seems to be more effective as opposed to the individual implementation thereof. Future research would make it possible to analyse the impact of rehabilitation on brain plasticity, in order to adapt treatment resources to meet the needs of each patient and to subsequently optimise the recovery process. More rigorous clinical and economic evidence is needed to incentivise practitioners and healthcare decision-makers to implement these NMES treatments. In addition, a multidisciplinary interactive effort between engineering, neuroscience and medicine is required to progress in the field of neurorehabilitation.

BIOGRAPHICAL SKETCH

Name: Trinidad Sentandreu-Mañó

Affiliation: Department of Physiotherapy, University of Valencia, Valencia, Spain

Education: Degree in Physiotherapy. Faculty of Physiotherapy, University of Valencia, Spain

Business Address: Department of Physiotherapy, Faculty of Physiotherapy, University of Valencia, Gascó Oliag 5, 46010 Valencia, Spain. E-mail: trinidad.sentandreu@uv.es

Research and Professional Experience:

Assistant professor. Department of Physiotherapy, University of Valencia.

Predocctoral training grant for researchers. Conselleria de Educació, Comunitat Valenciana, Spain. Foundation for the Promotion of Health and Biomedical Research (FISABIO), Valencia, Spain. Project entitled "Effects of neuromuscular electrical stimulation in the treatment of the elderly patient's hand with spastic hemiplegia after a stroke". File number ACIF/2012/017 (2012-2014).

Grant for research studies in technology and health practices based on scientific evidence. Conselleria de Sanidad, Comunitat Valenciana, Spain. Research Foundation of the Doctor Peset University Hospital, Valencia, Spain. Project entitled "Effect of electrical stimulation applied on the spastic hand in the elderly patients following a stroke". File number 004/2010 (2010).

ABSTRACT

The popularity of multimodal monitoring (MMM) in guiding treatment has grown over the past decade, despite slight evidence to support its use. Clarity is lacking about the indications for MMM, when it should be instituted, and how the collected data should be interpreted. Also in question are which MMM physiologic variables are most clinically pertinent and whether a monitoring-targeted approach improves outcomes. Although the contemporary concept of individualizing treatment based on patient-specific physiologic variables has gained increasing favor, few clinical data support this approach. Relying on therapy guided by monitoring of intracranial pressure and cerebral perfusion pressure is proving to be insufficient in addressing the pathophysiology of critical neurologic conditions. Understanding the limitations and challenges of MMM is crucial to interpretation of the data. Moreover, integration of the continuously monitored data and defining the phenotype of brain injury by a cumulative analysis are essential. The integration of MMM into clinical practice is evolving. Recently, several computational systems allowing the integration of the data into electronic medical records have been developed. The concept of individualizing physiologic parameter thresholds and regimen needs further prospective clinical validation.

INTRODUCTION

Care of patients undergoing decompressive craniectomy for traumatic brain injury or stroke lies in preventing and mitigating secondary brain injury through timely intervention, thus improving outcomes. To achieve the best outcome, appropriate physiological variables such as ICP, CPP, PRx, blood flow velocity, PbtO₂, lactate/pyruvate ratio are monitored and any significant changes are managed accordingly. Appropriate decision making is hindered when insufficient data are obtained from the neurological exam and neuroimaging. These static measures do not provide sufficient information on the dynamic pathophysiology that drives secondary brain injury. Data acquisition using several tools such as the neurological exam, neuroimaging, and systemic and neurophysiological parameters, i.e., multimodal monitoring (MMM), can guide individualized care. This approach is promising in detection of early changes before irreversible damage ensues. In this chapter, we discuss the different parameters for MMM, their integration in decision making, and the challenges and limitations they present to those using them.

INTRACRANIAL PRESSURE AND CEREBRAL PERFUSION PRESSURE

Some fundamental concepts undergird our understanding of the dynamic relationship between intracranial pressure (ICP) and cerebral perfusion pressure (CPP). The Monro-Kellie doctrine, for example, provides the conceptual basis for treating elevated ICP. Human intracranial volume is constant and is a sum of the volumes of cerebrospinal fluid, brain, blood, and mass lesion. An increase in the volume of any one of these components beyond the compliance of the brain inevitably leads to elevated ICP. Lundberg [1] introduced the concept of slow waves of ICP and interpretation of pathologic waveforms. Later, Langfitt et al. [2] and Lofgren and Zwetnow [3] introduced the pressure–volume curve and the term *compensatory reserve*.

ICP Wave Forms

The ICP wave form comprises three prominent components: pulse wave form, respiratory wave form, and slow waves. These components overlap in the time domain but can be separated in the frequency domain. The pulse wave form has several components of which the fundamental component correlates with heart rate and represents the mean ICP. The amplitude of this component is valuable in extracting various indices. ICP wave has pulsatile quality at two different frequencies, one synchronous with the arterial pulse and the other synchronous with the respiration. The respiratory waveform is related to the frequency of the respiratory cycle (8–20 cycles per minute). Slow waves commonly are not as explicit as in the original Lundberg thesis [1]. The cerebrospinal fluid pulse waveform is depicted in Figure 1. The three classically described patterns of ICP fluctuation reported by Lundberg are known as A, B, and C waves. Figures 2 and 3 depict Lundberg type A and B waveforms. C waveforms are not thought to have pathophysiological importance.

Pressure Volume Compensatory Reserve

The brain has a compensatory mechanism when there is an increase in one of the compartments with volume changes in the others. This compensatory mechanism defines the compliance of the brain. When these compensatory mechanisms fail, a small volume change can cause a significant ICP increase or even herniation. Compliance is vital since a patient with poor compliance is at a greater risk than one with good compliance, even if that patient's ICP is normal. The compensatory reserve can be plotted by defining the relationship between the mean ICP and changes in volume of the intracerebral space, known as the pressure–volume curve. This index is called the RAP [4], i.e., the correlation coefficient [R] between the amplitude [A] and the mean pressure [P]. An interpretation of RAP as an index delineates where the cerebrospinal system “working” point rests on the pressure–volume curve. An RAP coefficient nearing 0 signifies a lack of synchronization between changes in the amplitude of the fundamental component and the mean ICP. This represents a good pressure–volume compensatory reserve at low ICP, where a change in volume produces no or very minor change of the pressure. On the other hand, when RAP increases to +1, the amplitude of the fundamental component varies proportionally to the ICP. The curve of intracranial space shifts toward the right, toward the steep part of the pressure–volume curve. In this phase, the compensatory reserve is low and thus any additional increase in the volume will lead to a sharp rise in ICP.

Figure 1. Sketch indicating the three components of ICP monitoring tracing, (1): percussion wave (P1), tidal wave (P2), and dicrotic wave (P3). The percussion wave correlates with the arterial pulse transmitted through the choroid plexus into the cerebrospinal fluid, and via a column of fluid into the external ventricular drain (EVD) transducer. The tidal wave represents the cerebral compliance. The amplitude of P2 generally increases as compliance decreases, and when the P2 exceeds the P1 waveform, a marked decrease in cerebral compliance exists. The dicrotic wave correlates with the closure of the aortic valve, which makes the trough prior to P3 the equivalent of the dicrotic notch. (Courtesy of N Badjatia, University of Maryland).

Figure 2. Sketch indicates 2 classic Lundberg type A waves. These are steep rises in ICP to a plateau of 40 mm Hg or higher and are sustained for 5 to 20 minutes before falling rapidly. They represent a critical reduction in intracranial compliance. Plateau waves are associated with working cerebrovascular reactivity and low cerebrospinal compensatory reserve (Courtesy of N Badjatia, University of Maryland).

METHODS OF ICP MONITORING

ICP monitoring and treatment are best performed through a multimodal approach that encompasses clinical examination and imaging modalities. The intraparenchymal and intraventricular catheters are two preferred techniques in widespread use for ICP monitoring. Both are invasive devices and carry minimal risk of infection and bleeding when placed by skilled operators [5]. The intraventricular catheter is considered a gold standard and represents a global ICP assessment in comparison to the intraparenchymal monitor. In addition, it aids in cerebrospinal fluid diversion into the external ventricular drainage (EVD) and hence is an important resuscitation tool, especially in cases of acute hydrocephalus. It may have additional benefits with lower rates of refractory ICP and improved outcomes over intraparenchymal monitors [6]. The intraventricular catheter can also assist in delivering intraventricular drugs such as a thrombolytic for clearance of intraventricular hemorrhage [7]. Intraparenchymal monitors are relatively easier to place than intraventricular catheters. A major downside of intraparenchymal monitors is that they can give an inaccurate reading in cases where there is focal pathology leading to compartmentalization of ICP due to cerebral hemispheric and tentorial boundaries [8].

A change in baseline ICP readings, called a zero drift, associated with microtransducer systems in the intraparenchymal probes can result in measurement error over a certain period. In addition, parenchymal devices have limitations regarding recalibration *in vivo* and durability [9]. A recent meta-analysis showed both types of monitors yield similar average values, but interval values could differ [10]. Choice of which method to use is decided on an individualized basis and factors such as the etiology of the brain injury, coagulopathy,

accuracy, reliability, complication rates, and the cost associated with the devices [11]. With transition to electronic charting, a new paradigm of automated data collection allows for more accurate recording of data and holds intriguing future applications. Manual recording of ICP is not an accurate representation of the true pattern of unstable ICP in patients with traumatic brain injury (TBI) [12]. Automated continuous dynamic monitoring of mean arterial pressure (MAP) and ICP allows accurate prediction of episodes of intracranial hypertension and long-term outcomes in the neurosurgical intensive care unit [13].

Noninvasive Modalities for ICP Monitoring

Noninvasive techniques such as transcranial Doppler (TCD) and optic nerve sheath diameter (ONSD) have been utilized for ICP monitoring, especially when an invasive modality is contraindicated, not clearly indicated, or not available. TCDs can assess ICP through several methods including pulsatility index, noninvasive assessment of CPP, and several mathematical models. Depending on the method, there is considerable intra- and inter-group variability in reporting accuracy. Using the pulsatility index, Bellner and colleagues demonstrated encouraging results [14]. They cited a robust relationship between the pulsatility index and ICP with a correlation coefficient of $R = 0.94$ ($P < 0.05$). However, other studies have reported a weaker correlation between the pulsatility index and ICP [15, 16]. Studies have reported a similar variance in accuracy of monitoring ICP when using CPP estimation with TCDs. Czosnyka et al. estimated CPP using flow velocity and arterial blood pressure and reported a correlation coefficient of $R = 0.73$ between noninvasive CPP measurements and CPP measured through a parenchymal monitor. The estimation error was less than 15 mm Hg in up to 84% of cases [17]. TCD, however, is insensitive in cases where the elevation of ICP is not vasogenic in origin [18]. There can be technical difficulties in cases where an adequate acoustic window for artery insonation is not present. Precision of the tool is also dependent on operator skills. Despite of these limitations, TCD is good screening tool for ICP. ONSD can be measured using an ultrasound, and a 4.5- to 5.5-mm ONSD roughly correlates to an ICP of 20 mm Hg [19, 20]. ONSD has been shown to be much more predictive of ICP than computed tomography (CT) features in severe TBI patients [21]. The robust data on ONSD reported by Rajajee et al. [19] suggested an ONSD >4.8 mm correlated to an ICP >20 mm Hg with a sensitivity of 96% and a specificity of 94%. Other studies have reported a lower sensitivity and specificity [22]. Although ONSD is a quick tool to assess ICP, it provides only a snapshot of information. ONSD varies with individual factors such as age and underlying pathology, making it difficult to create a threshold for ICP treatment. This tool has good utility as a screening tool and in places lacking resources for continuous ICP monitoring. Another noninvasive approach of ICP measurement is an automated Neurological Pupil index obtained using a pupilometer. All of the above techniques have limitations, such as lacking the capability of continuous detection of changes, and need further clinical validation. Still, they serve as good screening tools and provide easy means of performing repeated assessments.

Indications for ICP Monitoring

The Brain Trauma Foundation (BTF) “Guidelines for the Management of Severe Traumatic Brain Injury” advocates monitoring ICP in all salvageable patients with a severe TBI (Glasgow Coma Score [GCS] 3–8 after resuscitation) and an abnormal CT scan (revealing hematomas, contusions, swelling, herniation, or compressed basal cisterns). This position was supported by Level IIB evidence [23]. ICP monitoring should be established in patients with severe TBI with a normal CT scan if two or more of the following features are noted at admission—age over 40 years, unilateral or bilateral motor posturing, or systolic blood pressure <90 mm Hg. The reason is that the incidence of intracranial hypertension was almost 60% when at least two of these features were present [24].

The consensus conference of recognized experts on ICP monitoring in TBI has made several additional recommendations [25]:

- Monitoring the ICP of comatose TBI patients with a normal initial head CT is generally not recommended. Repeat CT is recommended to rule out any new abnormalities after an early initial CT. Patients with new or worsening CT findings should be monitored.
- ICP monitoring is recommended following a secondary decompressive craniectomy to assess its effectiveness in controlling ICPs and to guide further therapy.
- ICP monitoring after evacuation of an acute supratentorial intracranial hematoma should be considered for salvageable patients with features associated with an increased risk of elevated ICPs. The following are the pre-operative and intra-operative clinical findings warranting ICP monitoring in supratentorial lesions: a GCS motor score ≤ 5 (the risk was felt to be even higher if ≤ 4); pupillary abnormalities (anisocoria or bilateral mydriasis); prolonged/severe hypoxia and/or hypotension; compressed or obliterated basal cisterns; midline shift exceeds 5 mm; midline shift exceeds thickness of an extra-axial clot; additional extra-axial hematomas, parenchymal injuries (such as contusions) or swelling and evidence of intraoperative brain swelling.
- Comatose patients with an initial CT scan demonstrating diffuse injury with signs of brain swelling (e.g., compressed/absent basal cisterns) should have ICP monitoring.
- Comatose patients with traumatic brain contusions, in whom the interruption of sedation to check the neurological status is considered dangerous or when the clinical examination is not completely reliable, should be subjected to ICP monitoring.
- Primary decompressive craniectomy (i.e., absence of bone flap) is not a sufficient reason for not monitoring the ICP in the postoperative period if any indications for ICP monitoring are present.

ICP Monitoring in Traumatic Brain Injury and Outcomes

CPP optimization and control of raised ICP are fundamental in addressing the primary and secondary pathophysiologic processes in TBI. ICP is an important marker of injury

severity in TBI [26]. Increased ICP is associated with mortality and poor outcomes [26-30]. Even transient episodes of ICP elevation are associated with poor outcomes [30]. In addition, the pattern and duration of rise and the total dose of ICP are consequential in defining outcomes [27, 31, 32]. ICP treatment responsiveness or refractoriness also affects outcomes [26, 33].

As indicated by the BTF guidelines, moderate quality data exist from multiple observational studies demonstrating benefits of treatment guided by ICP monitoring in the form of decreased in-hospital and 2-week post-injury mortality [34-37]. Aggressive ICP-guided care has also been shown to be more cost effective than routine care [38]. The consensus summary statement of the International Multidisciplinary Consensus Conference on Multimodality Monitoring in Neurocritical Care mandates ICP monitoring when other intracranial monitors are used, to provide a framework for optimal interpretation [11]. Retrospective studies [39, 40] emphasize the importance of monitoring ICP post-decompressive craniectomy, having found better outcomes in the group where the management strategy was based on ICP monitoring.

The Benchmark Evidence from South American Trials: Treatment of Intracranial Pressure (BEST TRIP) showed no superiority of treatment based on ICP monitoring versus intervention based on protocolized neurological exam and imaging [41]. ICP-guided treatment was, nonetheless, more efficient in treating ICPs than the other approach. BEST TRIP, however, was not a trial of ICP monitoring or the efficacy of ICP monitoring, but rather a study of two methods of severe TBI management. The results were informative on the need for further study on selection of patients for ICP monitoring, determination of patient-specific ICP thresholds, and development of treatment protocols and strategies [42].

The recent RESCUEicp trial (Randomised Evaluation of Surgery with Craniectomy for Uncontrollable Elevation of ICP) [43] addressed some of the key limitations of the DECRA (Decompressive Craniectomy) trial evaluating the role of decompressive craniectomy for management of refractory ICP [44]. The RESCUEicp trial compared last-tier secondary decompressive craniectomy with continued medical management in patients with a higher ICP threshold (25 mm Hg for 1 to 12 hours) despite maximal medical treatment except for barbiturates. The study showed benefit in the surgical arm in terms of lower mortality, but a higher number of patients in a vegetative state or with severe disability. The RESCUEicp trial was effective in reducing refractory ICPs, but provided no benefits to the pathophysiology of primary neurologic insult.

Despite current recommendations and clinical practice, Level 1 evidence is lacking on whether therapy guided by ICP monitoring makes a difference in clinical outcome. There is no randomized control trial (RCT) addressing treatment threshold in TBI. The data on target ICP number are derived from several observational studies [23, 24, 45]. An increase in ICP above 22 mm Hg is associated with unfavorable outcomes [46], and is currently the treatment threshold in the BTF guidelines as a Level 2B recommendation [23].

Although CPP can be derived by monitoring ICP, the adequacy of cerebral perfusion cannot be reliably determined by an ICP number. Secondary brain injury can occur even with normal ICP and CPP numbers [47]. Bouzart et al. [48] made this point emphatically by showing that MMM incorporating brain tissue partial pressure of oxygen monitoring in addition to ICP can identify cerebral hypoperfusion more reliably than ICP monitoring alone.

The ICP value is dependent on the interplay of several factors, including cerebral compliance, perfusion, oxygenation, and cellular functioning, that vary in different

pathophysiological states. In addition, the intensity of the treatment is driven by patient's response/resistance to treatment, which predicts the severity of the insult in several disease states but does not alter the underlying pathology. Hence, targeting isolated CPP/ICP addresses the supply to brain without considering the underlying cerebral metabolism.

Treatment decisions regarding ICP tend to focus on individualizing thresholds based on patient characteristics, cerebral physiology, and risk–benefit considerations. The approach of treating ICP thresholds is not pathophysiology-specific and is a generalized measure. Hence, the approach to ICP treatment is more phenomenological than mechanistic. It does not allow individualizing therapy and is more reactive than proactive. This underlines the significance of MMM to intervene appropriately on pathophysiological states and individualizing care rather than merely treating an ICP number.

CEREBRAL BLOOD FLOW, CEREBRAL PERFUSION PRESSURE, AND ISCHEMIA

Hypotension significantly impacts outcomes after TBI [49, 50]. Adequate perfusion to the brain is essential in preventing secondary brain injury driven by hypoxia, ischemia, and cerebral metabolism.

Cerebral Blood Flow

Cerebral blood flow (CBF) is regulated and affected by several varied factors such as arterial blood pressure, intracranial pressure, venous outflow, blood viscosity, partial pressure of carbon dioxide or oxygen in arterial blood (PaCO₂ and PaO₂, respectively), collateral flow, vasoreactivity, and the status of cerebral autoregulation. Alterations in the PaCO₂ exert a profound influence on CBF, with an approximately 4% change in CBF for every 1-mm Hg change in PaCO₂ in either direction. This arteriolar response is mediated by a local effect of H⁺ ions or pH fluctuations in the extracellular fluid surrounding vessels in the brain [51]. The PaO₂ in the normal physiological range does not affect CBF, but when PaO₂ falls below 50 mm Hg, CBF increases dramatically. CBF can be measured both directly and indirectly; however, direct measurement is challenging. For this reason, surrogate variables have been used to monitor and treat patients with TBI and stroke. CBF can be directly measured using a thermal diffusion probe (Hemedex) inserted into brain parenchyma. The probe measures the thermal gradient between the distal thermistor and the proximal temperature sensor, providing a regional CBF measured in milliliters/100 grams brain tissue/minute. Normal CBF in humans varies widely depending on tissue demands and age, but averages around 50 mL/100g/minute. Irreversible neuronal damage occurs in a time-dependent manner when CBF is below 10–15 mL/100 g/minute, whereas reversible neuronal dysfunction has been noted at a CBF between 15 and 20 mL/100 g/minute.

TCD is a well-studied, noninvasive, and easily reproducible tool for estimating CBF. TCDs provide an indirect estimate of CBF based on flow velocity through a cerebral vessel. A linear relationship exists between CBF and middle cerebral artery flow velocity if the cross-sectional area and angle of insonation are constant. The Lindegaard ratio [52], the ratio

of the middle cerebral artery velocity to the internal carotid velocity, can signify if the increase in the middle cerebral artery (MCA) velocity is related to vessel narrowing.

The strategy of hyperventilation is often used in the acute setting of TBI and elevated ICP. Excessive hyperventilation in TBI can result in ischemia and is associated with poor outcomes [53, 54]. An end tidal CO₂-guided hyperventilation strategy and assessment of CBF can therefore be crucial in these patients. In addition, CBF assessment is also crucial in patients requiring sedation and paralysis with mechanical ventilation. TCDs can help estimate CBF at bedside under these circumstances.

Although positron emission tomography (PET) is the accepted gold standard for assessment of CBF and brain metabolism, its prohibitive cost and limited accessibility in many trauma centers have restricted the widespread clinical use of PET in the acute setting. As an alternative, xenon-enhanced CT has been validated as a method for measuring CBF and guiding management in TBI [55-57]. Xenon-enhanced CT provides a measurement of the CBF. Ischemia within 6–12 hours following trauma as detected by xenon CT studies in TBI patients has been associated with adverse long-term outcome [58].

Arterial spin labeling (ASL) is a magnetic resonance imaging (MRI) technique that enables the measurement of brain perfusion noninvasively at the tissue level. ASL works on the principle of magnetically labeled blood obviating the need of contrast. ASL is a sensitive modality to detect structural brain damage and outcome in mild TBI [59]. Application of ASL depicts mismatch perfusion in acute stroke and helps identify tissue at risk in chronic cerebrovascular disease. ASL can be used to estimate the cerebrovascular reserve and future risk of cerebrovascular events [60].

Cerebral Perfusion Pressure

CPP is defined as the difference between the MAP and the ICP. This represents the pressure gradient driving CBF and hence oxygen and metabolite delivery. The current BTF guidelines on CPP recommend a threshold of 60–70 mm Hg in TBI patients [23]. Different strategies to optimize CPP in TBI patients have been studied [61, 62]. Patients who have an impaired autoregulatory status will have increased cerebral blood volume and increased risk of secondary brain injury with higher CPPs due to elevated ICPs and hyperemia [63]. Loss of autoregulation puts the patient at risk of secondary brain injury via ischemia with hypotensive episodes. On the other hand, patients with intact autoregulatory status would be better served with higher CPPs. Depletion of the cerebrovascular reserve and impaired autoregulation leads to direct dependence of CBF on CPP; hence the CBF may still be suboptimal despite the CPP being within normal range [64]. The adequacy of the CBF and CPP is also dependent on the cerebral metabolic oxygen consumption. Despite decreased CBF, there would be no ischemia if the cerebral metabolic rate of oxygen (CMRO₂) is decreased (e.g., in sedation). To the contrary, when CBF reduction is greater than the CMRO₂, ischemia and eventually secondary brain injury ensue. The ultimate goal for CPP depends on the autoregulatory status of the patient. Optimal CPP, i.e., the range of CPP at which the autoregulatory status is intact, can be calculated using the pressure reactivity index (PRx). Several studies have assessed the relationship between optimal CPP, neurologic outcomes (65-68), and physiologic outcomes [64] in TBI. Jaeger et al. demonstrated that CPP above optimal has no benefit on brain tissue oxygenation after TBI [64]. Large deviations from CPP above optimal on either side are

associated with poor outcomes [68]. CPP augmentation puts patients at risk for systemic complications (e.g., ARDS), for demand ischemia in other organs, and for poor outcomes [62, 69]. Targeting optimal CPP can be much more effective than having a range of CPP thresholds in preventing secondary brain injury and complications. However, there still is not enough evidence to incorporate a single number for CPP into clinical practice [70].

Cerebral Autoregulation

Under normal physiological conditions, cerebral autoregulation is a complex process that is a byproduct of the interplay between myogenic, neurogenic, and metabolic mechanisms. Cerebral autoregulation is a protective hemodynamic mechanism developed to protect the brain from changes in CPP causing either hypoperfusion or hyperperfusion. Autoregulation normally maintains MAP between ~ 50 and 150 mm Hg. Normal CBF in humans varies widely depending on tissue demands and age but averages around 50 mL/100 g brain tissue/minute. Acute brain injury, however, often leads to dysfunctional autoregulatory mechanisms lasting up to 2 weeks [71]. The assessment of pressure autoregulation can be classified as static or dynamic [72]. Static assessment illustrates changes in the CBF measures due to fluctuations in MAP. Dynamic assessment takes into account the time factor when looking at changes in CBF in response to MAP. There are two fundamental approaches to optimizing therapy and treating patients with TBI. One approach is the Lund concept [73, 74] that is based on managing increased ICP and regulating cerebral volume. The other is an aggressive CPP management [61] to prevent ischemia and secondary brain injury. Howells et al. [75] suggested that the most appropriate of the two approaches for individual patients may depend on the state of cerebrovascular PRx. PRx is a dynamic assessment of autoregulation.

Pressure Reactivity Index

Cerebrovascular pressure reactivity is the ability of vascular smooth muscle to respond to changes in transmural pressure. As described by Czosnyka and colleagues, PRx is a computer-aided method of calculating a correlation coefficient between 40 past consecutive 5-second averages of ICP and arterial blood pressure (ABP); computations were repeated with a moving window every 5 seconds [76]. Current standards for computing PRx in monitoring are modified to a moving correlation coefficient between 30 values of consecutive 10-second ABP and ICP averages. If pressure reactivity is intact, a rise in MAP will lead within 5–15 seconds to vasoconstriction with reduction in cerebral blood volume, and thus will lower ICP. If there is dysregulation in pressure reactivity, cerebral blood volume will increase passively, and ICP will rise. When there is a reduction in MAP, the opposite takes place. This technology has been used to develop individualized thresholds for ICP and CPP above optimal. Information on pressure reactivity can potentially guide treatment decisions for intracranial hypertension based on the cerebral physiology.

A positive PRx suggests a positive association of ABP and ICP, reflecting a passive non-reactive vascular bed (Figure 4). A negative value of PRx reflects a normally reactive vascular bed, representing an inverse association between ABP and ICP. Patients can have impaired autoregulation even with mild TBI, making them more susceptible to hypotension.

Impaired cerebral autoregulation will lead to sudden increases in MAP being easily transmitted into the microcirculation and can contribute to secondary brain injury in the form of ischemia/ infarction, hyperemia, cerebral edema, or cerebral hypoxia [63]. Furthermore, cerebral autoregulation determines the response to the treatment administered to a patient with severe TBI, including hyperosmolar therapy and vasopressors. A positive PRx correlates significantly with high ICP, low admission GCS score, and poor outcome at 6 months after injury [76]. PRx correlates well with cerebral autoregulation flow velocity in TCD ultrasonography, static rate of autoregulation based on TCD.

Figure 3. Sketch indicates Lundberg type B waves. Lundberg type B waves occur with a frequency of 0.5 to 2 Hz and are rhythmic oscillations to 20–30 mm Hg above the baseline but without a sustained period of intracranial hypertension (Figure 3) (Courtesy of N Badjatia, University of Maryland).

The PRx has been validated against a PET-derived static rate of autoregulation based on PET and oxygen extraction fraction [77]. Patient-specific ICP thresholds calculated based on PRx and the total ICP dose were shown to be more robust predictors of 6-month clinical status and mortality than the conventional thresholds of 20 and 25 mm Hg [78]. In patients after decompressive craniectomy, PRx might not be as useful unless clearly positive, because of the considerably high compliance of intracranial cavity after skull opening. Limitations of the PRx lie in measuring accurate MAPs and CPP calculations, which can have significant implications for treatment based on them [79]. Despite optimal CPP/ICP numbers, cerebral hypoxia can still occur [80, 81]. Studies assessing the interplay between cerebral microdialysis, PET imaging, and brain tissue oxygen tension (PbtO₂) monitoring have demonstrated that despite normal ICP/ CPP parameters, cerebral hypoxia and secondary brain injury can occur [47, 82–84]. A CPP/ICP-targeted approach might therefore be suboptimal in TBI patients. For this reason, there has been a recent emphasis on characterizing the cerebral physiology and metabolism and on individualizing treatment based on the patient's clinical profile. This approach could offer an edge in guiding therapy and preventing potential deleterious side effects of the treatment strategies (Figure 5).

Figure 4. Sketch indicating a positive correlation coefficient (pointed out by the long arrow at 16:45) between changes in mean ICP and MAP (PRx) which signifies poor pressure-reactivity of cerebral arterioles (Courtesy of N Badjatia, University of Maryland).

Figure 5. Example of MMM changes preceding hemicraniectomy in a subarachnoid hemorrhage patient (reference: Stuart et al. *Neurocrit Care* (2011) 15:146–150). Intracranial pressure (ICP), cerebral perfusion pressure (CPP), mean arterial pressure (MAP), lactate: pyruvate ratio (LPR), and brain tissue oxygen tension (PbtO₂) trends for post-bleed days (SAH days) 2–8. Infusion rates of norepinephrine and vasopressin are also displayed, as well as timing of head CT's. Before craniectomy, note the decrease in CPP and MAP despite increasing rates of norepinephrine and vasopressin, as well as the early rise in LPR >40, decrease in CPP <40 mm Hg, and late decrease in PbtO₂ <25 mm Hg. In the hours immediately preceding hemicraniectomy, the LPR was actually greater than the CPP. After craniectomy, ICP was maintained <25 mm Hg and CPP >60 mm Hg, and all pressors were weaned to off within hours. The PbtO₂ probe malfunctioned immediately post-surgery (Courtesy of N Badjatia, University of Maryland).

Brain Oxygenation

While PET is considered the gold standard in monitoring brain tissue oxygenation, other modalities include jugular venous oxygen saturation (SjVO₂), brain tissue oxygenation (PbtO₂), oxygen reactivity index (OR_x), near-infrared spectroscopy (NIRS), and MR spectroscopy. Imaging modalities provide snapshots of information versus dynamic information obtained through continuous modalities. BTF guidelines recommend placement of a brain oxygenation monitoring device when hyperventilation strategies are employed. More recent MMM guidelines recommend placement of a PbtO₂ device in patients at risk for ischemia [11, 23].

SjVO₂

Oxygenation of cerebral venous outflow has been utilized as a neuromonitoring modality for several decades [85, 86]. SjVO₂ provides an estimate of global cerebral oxygenation status and adequacy of the CBF. The jugular bulb, the dilated portion of the jugular vein just below the base of the skull, is the preferred site for blood sampling. Even though the jugular bulb drains bilateral hemispheres, usually the right internal jugular vein is the dominant side of drainage, making it the preferred side for insertion in diffuse disease processes. In cases of a focal brain injury, it is controversial whether the catheter insertion site should be ipsilateral to the brain injury side or on the dominant side, if a difference exists. There is significant disparity between two jugular vein oxygen saturation measurements [87]. Needle puncture, retrograde central venous catheter into the jugular vein, or insertion of a fiber optic catheter all allow for a continuous SjVO₂ monitoring. Skull x-ray can be used to confirm placement. On a lateral neck radiograph, the catheter tip should be at the level of and just medial to the mastoid process.

Important formulas related to the physiology of brain oxygenation and utilization are as follows:

$$DO_2 = CBF \times CaO_2$$

$$CMRO_2 = CBF (CaO_2 - CjvO_2)$$

$$A_jvDO_2 = CMRO_2 \div CBF$$

$$CBF = \frac{\Delta P}{4 \pi r^4 \eta L}$$

$$\text{Arterial Oxygen content} = (1.34 \times Hgb \times PaO_2) + (0.0031 \times PaO_2)$$

where DO₂ = delivery of oxygen, CBF = cerebral blood flow, CaO₂ = arterial oxygen content, CMRO₂ = cerebral metabolic rate of oxygen, CjVO₂ = jugular venous oxygen content, Hgb = hemoglobin, SjVO₂ = jugular venous oxygen saturation, A_{jv}DO₂ = difference in oxygen content between arterial and jugular venous blood, PaO₂ = arterial oxygen saturation, r = radius, P = pressure, Z = viscosity, and L = length. CBF is governed by Poiseuille's law.

Normal SjVO₂ ranges from 55% to 75%. SjVO₂ is an indirect assessment of cerebral oxygen consumption. When demand exceeds supply, the brain extracts greater oxygen, resulting in decreased jugular bulb oxygen saturation. If CBF decreases, eventually the compensatory mechanism of increased oxygen extraction in response to decreased CBF will fail and result in anaerobic metabolism with lactate production. When cerebral oxygen supply exceeds demand, SjVO₂ is elevated.

SjVO₂ monitoring has numerous clinical implications. For one, it promptly diagnoses ischemia resulting from either cerebral or systemic causes [88-92]. SjVO₂ < 55% suggests ischemia or increased metabolism and oxygen extraction, whereas SjVO₂ > 75% indicates hyperemia and decreased metabolic demand. Low values are associated with poor outcomes especially in the setting of no improvement with CPP augmentation [93]. SjVO₂ can guide treatment decisions regarding fluid strategy, optimization of CPP and oxygenation [11, 23, 89], and detecting arteriovenous fistulas [94]. ICP management, including utility of barbiturates [95] for suppressing cerebral metabolism, is also guided by SjVO₂ monitoring [11, 23].

Complications associated with SjVO₂ include carotid artery puncture, pneumothorax, injury of cranial nerves IX and X, infection, and thrombosis. Appropriate placement of the catheter in the jugular bulb is crucial to avoid extracranial contamination and inaccurate information. The interpretation of SjVO₂ and CBF can be challenging by itself, since the assumption is that the CMRO₂ remains constant. In addition, SjVO₂ can be insensitive to focal ischemia. High SjVO₂ values can be falsely reassuring because they may, in fact, be associated with pathologic arteriovenous shunting, brain death, or cerebral infarction.

PbtO₂

PbtO₂ has become the gold standard for monitoring brain oxygenation. The limitations of CPP/ICP monitoring to detect ischemia/hypoxia are avoided by PbtO₂ monitoring [48]. It assists in better understanding the underlying pathophysiology of secondary brain injury. PbtO₂ is affected by oxygen demand and supply including perfusion and oxygenation [96-99]. However, several factors such as relative proportion of arterial and venous supply in the region of interest (shunting) and diffusion barriers (interstitial/cellular edema) [100], cerebral metabolism (fever, seizures, shivering), and systemic factors like PaCO₂, PaO₂ [101-104] affect PbtO₂. Hence, PbtO₂ is more of a marker of cellular and mitochondrial functioning. Rosenthal et al. showed that a PbtO₂ number is the result of CBF and the arteriovenous oxygen tension difference rather than being a surrogate of cerebral metabolism and oxygen delivery [105]. That PbtO₂ can be low despite a normal CBF suggests microcirculatory collapse and edema [100]. This can be clinically significant when assessing MMM data to guide treatment.

Normal PbtO₂ ranges from 25 to 35 mm Hg [106-108], with the most recent MMM guidelines suggesting 20 mm Hg as the treatment threshold [11]. Ischemic thresholds have ranged between 10 and 19 mm Hg in the literature [109-111]. PbtO₂ < 5 mm is associated with cell death [112-114]. The clinical significance of the PbtO₂ number varies based on the probe placement [109]. When the probe is placed in the normal tissue and autoregulation is intact, PbtO₂ has a good correlation with CPP. In penumbral tissue, the correlation with CPP can be inconsistent. When placed in dead tissue, there is no correlation with CBF/ CPP.

PbtO₂ has various methods of measurement. Biomedical engineering includes optical luminescent and polarographic methods. The polarographic method is much more common, and has been used in the development of the LICOX® (Integra Neurosciences, Plainsboro, NJ) brain tissue monitoring system, commonly used in clinical practice. The NEUROVENT®-PTO (Raumedic Co., Mills River, NC) multimodal catheter uses optical luminescence methodology. The LICOX monitor is inserted into the brain parenchyma like a fiber optic ICP monitor, generally 3.5 cm below the dura in the frontal white matter. It measures the partial pressure of oxygen around the catheter insertion site, which measures

about 17 mm³ of brain tissue around the distal end. In TBI, the monitor is usually inserted into the normal brain tissue in the frontal lobe ipsilateral to the severely injured brain. In cases of diffuse injury, the monitor is usually inserted into the non-dominant hemisphere.

PbtO₂ monitoring has numerous clinical implications. In TBI, several observational studies have reported the effect of brain hypoxia on outcome. The presence of cerebral hypoxia has been associated with unfavorable outcomes at 6 months and increased mortality [47, 115-117]. Increasing duration of hypoxia [111] and early hypoxia within the first 72 hours after brain injury [118] have been shown to predict mortality. The duration and burden of brain tissue hypoxia have also been associated with worse outcome at 30 days [47, 84]. PbtO₂ has been established as an independent predictor of outcomes. Low PbtO₂ is not specific for simple perfusion failure. Factors such as PCO₂, PaO₂, and hypermetabolic states can all affect PbtO₂. PbtO₂ number signifies a balance between supply, which is dependent on perfusion, and demand, which is the magnitude of oxygenation and extraction. Although a PbtO₂-guided intervention strategy in TBI has been studied, the data on outcome benefits are still unclear [119-122]. The BTF guidelines recommend PbtO₂ monitoring in patients with severe TBI to complement ICP/ CPP monitoring [23]. PbtO₂ monitoring can be used to individualize thresholds for CPP in conjunction with ICP monitoring [123].

ORx

The oxygen reactivity index (ORx) is a surrogate of pressure autoregulation and has some prognostic value. The potential to improve PbtO₂ using vasopressors by increasing the MAPs and CPP is dependent on the status of cerebral autoregulation. When the autoregulation is intact, increasing the CPP usually has a negligible effect on the PbtO₂, and compensatory vasoconstriction leads to the CBF and oxygen delivery remaining constant. In the event of the autoregulation being impaired or when the CPP is outside the autoregulatory range, either too low or too high, CBF and brain PbtO₂ correlate directly with CPP augmentation, leading to elevation in brain PbtO₂. The ORx is calculated as the moving linear (Pearson) correlation coefficient between PbtO₂ and CPP and ranges from +1 to -1. When autoregulation is intact, ORx is near 0 or negative. When autoregulation is impaired, PbtO₂ passively follows CPP, and ORx is positive. Recent studies, however, have refuted the relationships between PRx and ORx and between ORx and PbtO₂ [124].

ORx has the advantage of being one of the most effective real time bedside monitoring tools available for detecting focal ischemia. It provides focal monitoring for tissue at risk of secondary brain injury, and it is a relatively safe modality. But its use does have limitations. Because it is a focal invasive monitor, ORx can miss distant changes in the tissues. It can have sensitivity drift requiring recalibration. There is a “run in” period immediately after the probe insertion, when the readings are inaccurate. “Oxygen challenge” should be performed daily post insertion to verify accurate functioning of the probe. Placing the probe into the precise location is challenging, and the probe can give an inaccurate assessment if it is inserted into the lesion instead of viable tissue. Critical thresholds have been ascertained through patient outcomes in small studies rather than pathophysiologic evidence of ischemic damage at the cellular level.

NIRS

Near-infrared spectroscopy (NIRS) in the TBI population is best applied in detection of mass lesions, midline shift, and cerebral edema because of high sensitivity [125]. NIRS is

most suitable for use in the outpatient setting for early detection, resuscitation, and quick transfer of patients to well-equipped tertiary centers. Use of NIRS to detect intracranial pathology in the inpatient setting is not widespread owing to readily available CT scan and imaging modalities.

Although the application of NIRS in monitoring ICP has been studied, the exact relationship between information obtained from NIRS and severity of ICP is not quite clear [126, 127]. In addition, there is no convincing evidence that NIRS can be reliably combined with any other invasive monitoring modality (ICP, tissue oxygen tension, jugular bulb saturation), and NIRS cannot be used in place of these modalities when they are indicated. The correlation of PbtO₂, SjvO₂, and microdialysis with the information obtained from NIRS data is inconclusive. The use of NIRS in TBI is therefore not widespread, owing to concerns about extracranial tissue and lesions interfering with the modality. Current devices monitor change in brain oxygenation. Another limitation of NIRS is that the thresholds for ischemia/hypoxia are not well determined.

Systemic Oxygenation

Systemic venous oxygenation is not a surrogate of SjVO₂. The brain receives approximately 15% to 25% of the total cardiac output and has a high extraction capacity and a low oxygenation reserve compared to other organs. Brain PbtO₂ correlates with systemic oxygenation and PaO₂. For example, acute lung disease will lead to a lower brain PbtO₂, independent of cerebral and systemic injuries [128]. The ratio of the change in PbtO₂ to the change in PaO₂ is described as the tissue oxygen response. The brain responds to hyperoxia in the form of cerebral vasoconstriction [129, 130], thus reducing CBF, a brain protective mechanism related to oxygen toxicity. The tissue oxygen response is another marker of cerebral autoregulation, like PRx and ORx.

Cerebral Metabolism and Microdialysis

Cerebral metabolism, which is significantly altered in acute brain injury, is roughly divided into three phases after brain injury: hypermetabolism lasting hours to days, hypometabolism lasting days to weeks, and transition into normal metabolism lasting weeks to months (this third phase is less well established) [131]. MMM guidelines recommend cerebral microdialysis as a clinical tool in patients with or at risk of cerebral ischemia, hypoxia, energy failure, and glucose deprivation [11].

Cerebral microdialysis requires that a specialized catheter with a semipermeable dialysis membrane be placed into the brain parenchyma through a burr hole and secured by a cranial bolt. The catheter is perfused with a cerebrospinal fluid-like solution, and sampling of brain extracellular fluid is conducted periodically to assess concentrations of lactate and pyruvate, ischemic metabolites, glucose, glycerol, markers of cell membrane damage, glutamate, and excitatory amino acid. The best of these biomarkers is the lactate/pyruvate (L/P) ratio, which implies a shift from aerobic to anaerobic metabolism and has prognostic significance [11]. L/P ratios >25 have been suggested as critical thresholds for metabolic crisis [132, 133]. Metabolic crisis can occur despite normal ICPs [132] and is associated with poor outcomes.

Energy crisis has been found to occur, characterized by normal PbtO₂ and elevated lactate with normal/low pyruvate levels, without evidence of ischemia or defect in oxygen delivery related to mitochondrial dysfunction [82]. In addition, L/P ratio has been associated with several causes such as low CPP [134] and thresholds of hemoglobin [135]. Hence, the L/P ratio can have significant clinical implications when using strategies to maximize perfusion.

Several diverse types of brain tissue hypoxias and neuromonitoring profiles have been described in the literature ([136, 137] Table 1). PET studies have found a variable relationship between cerebral metabolic rate for oxygen, L/P ratio, and oxygen extraction fraction depending on the location of the probe, timing of monitoring, and thresholds for ischemia [82, 138]. The type of hypoxia defines the relationship between L/P ratio and oxygen extraction fraction [139]. Interpretation of dialysate components might be confounded by drugs, nonconvulsive status epilepticus, and enzyme deficiencies (140). A reduced brain/serum glucose ratio [141] signifies metabolic crisis and can help differentiate other confounders causing high L/P ratio. In defining critical causes of cerebral perfusion, Bouzat et al. [48] defined a better role for PbtO₂ and cerebral microdialysis than ICP monitoring alone. The safety profile of cerebral microdialysis used to determine L/P ratio is similar to any other probe in MMM. Because it provides a focal measurement, its limitations lie in the metabolic collection assessment based on the location between injured and preserved brain. Cerebral microdialysis is a cumbersome technique and metabolite collection occurs over time. Hence, the data interpretation and usage can be delayed. Moreover, the benefits of targeting L/P ratio thresholds in terms of outcomes are unclear. The ideal location for regional monitors of MMM has not been identified. Conventional practice is placement in brain parenchyma at the greatest risk for secondary injury. For focal injury, such as ischemic stroke or traumatic intracerebral hemorrhage or contusion, that location is directly adjacent to the damaged area. In global injury, the non-dominant frontal cortex is used.

Table 1. Neuromonitoring profiles and treatment approaches, by category of brain tissue hypoxia

Category of hypoxia	Neuromonitoring profile	Treatment approach
Ischemic	↓CBF, ↓CPP ~ ICP ↓ PbtO ₂ ↑LPR	CPP augmentation with fluid and/or vasopressors Improve oxygen delivery
Hypermetabolic (Demand supply mismatch)	↑CBF, ↑CPP ~ ICP ↑PbtO ₂ ↑LPR	Evaluate and treat for causes such as fever, shivering, ictal-interictal EEG patterns

Electrophysiology

Electroencephalography (EEG) is a noninvasive, continuous modality utilized in detecting seizures, ischemic changes, new structural lesions, and recovery of altered mental status following TBI or stroke. EEG provides information on global and regional cerebral functioning. The rationale for long-term EEG monitoring lies in detecting subclinical seizures as an etiology for altered mental status or coma. In addition, it is hoped that early detection

and suppression of seizures, either convulsive or nonconvulsive, would translate into improved outcomes [11, 142, 143]. Incidence of nonconvulsive seizures in TBI has been reported to be up to 22% (144), whereas the incidence of early seizures in acute stroke ranges from 3% to 33%, with 50% to 78% of the seizures occurring within the first 24 hours [145]. Occurrence of seizures within 24 hours of stroke is associated with higher 30-day mortality [145]. Vespa et al. [146] demonstrated a high incidence of nonconvulsive status epilepticus and a relationship between acute posttraumatic nonconvulsive status epilepticus and disproportionate long-term hippocampal atrophy.

Fluctuations in CBF have been linked to changes on the EEG [147], (Figures 5 and 6) and different cellular responses. When CBF drops to 25–35 mL/100 g/minute, the EEG first loses faster frequencies due to anaerobic metabolism and glutamate release at a cellular level. As CBF continues to plummet to about 17–18 mL/100 g/minute, slower frequencies increase, with generation of lactic acidosis and depletion of ATP at the cellular stage. This represents an ischemic threshold (reversible). As CBF declines to 10–12 mL/100 g/minute and lower, sodium-potassium pump failure, an increase in cellular water content, and eventually cell death take place. Cell death is marked by severe suppression on continuous EEG. Diffusion-weighted imaging (DWI) is capable of detecting ischemic changes in stroke at CBF 35–40 mL/100 g/minute within 30 minutes [148]. In comparison, continuous EEG can detect ischemic changes within seconds and provide a window of opportunity to intervene, especially in the case of a mismatch between DWI-identified lesions and clinical assessment.

Figure 6. A short strip EEG belonging to a subject following TBI manifesting radiographic evidence of left internal carotid artery (ICA) vasospasm due to post traumatic subarachnoid hemorrhage. There is evidence of slowing of electrical waves over the left hemisphere (Leads with odd numbers) (Courtesy of N Badjatia, University of Maryland).

Figure 7. Quantitative analysis of EEG belonging to a subject following TBI manifesting radiographic evidence of left internal carotid artery (ICA) vasospasm due to post traumatic subarachnoid hemorrhage. There is evidence of difference in the Alpha Delta Ratio (ADR) between the left (0.569) and right hemisphere (0.872) (Courtesy of N Badjatia, University of Maryland).

EEG can assist in guiding treatment with either tissue plasminogen activator [149, 150] or augmentation of blood pressure or CBF after an acute ischemic stroke [151]. Quantitative EEG limits subjectivity in EEG interpretation, obviating the need for trained personnel to interpret EEG in the intensive care unit. With Fourier transformation, EEG can be quantified in terms of its amplitude, power, frequency, and rhythmicity, and numerical values, ratios, or percentages can be obtained. When applying quantitative EEG in acute ischemic stroke, the hemispheric relative delta percentage and the overall mean frequency correlate well with CBF [152]. Increase or decrease in the power of slower and faster frequencies varies with the changes in the cerebral metabolism [153]. Continuous EEG can be used to monitor neuropathological mechanisms and to detect markers of secondary brain injury [154] (Figures 6 and 7). These markers are manifested as periods of isolated or continuous depression in the form of high amplitude delta activity induced by spreading cortical depolarization, a feature of all acute brain injury. There are some data on the role of EEG in prognostication in patients with acute brain injury (TBI/stroke). Loss of reactivity [155] and lack of sleep-wake cycles [156] may portend poor prognosis (and indicate possible brainstem involvement). On the other hand, the presence of faster frequencies within 24 hours is consistent with a good outcome [157].

Glucose and Nutrition

Early sympathetic surge related to brain injury can cause dysfunction of glucose control. Hyperglycemia not only is a marker of disease severity in TBI but also can worsen secondary injury. In a study conducted on 59 patients with moderate and severe brain injuries, serum glucose levels >200 mg/dL in the first 24 hours after hospital admission were associated with worse neurologic outcome at hospital discharge, 3 months, and 1 year following trauma [158]. Cerebral microdialysis holds great promise in helping to understand the

pathophysiology of metabolic demand after brain injury and thereby providing an individualized goal. Studies using microdialysis have shown that tight glucose control can exacerbate brain metabolic crisis [159]. In ischemic brain injury, hyperglycemia has been associated with worse outcomes [160]. The Stroke Hyperglycemia Insulin Network Effort trial [161] will be informative in terms of the range of blood glucose to target in acute ischemic stroke.

Temperature and Inflammation

Target temperature management in TBI has been studied under two hypotheses. The first concerns mitigating secondary brain damage caused by ischemia/reperfusion injury and inflammation. The second is based on the role of hypothermia in ICP management. The National Acute Brain Injury Study: Hypothermia (NABIS:H) found no evidence of improved outcomes (Glasgow Outcome Scale at 6 months) in patients who were maintained on a hypothermia regimen for 48 hours after injury [162]. In a later report, NABIS:H II did not show any beneficial effect on morbidity or mortality for patients with severe brain injury [163]. However, subanalyses of RCTs and some animal data suggest a benefit of early, preoperative hypothermia in patients with focal brain lesion [164]. An international multicenter RCT (HOPES trial) is underway assessing the role of hypothermia in acute subdural hemorrhage. More recently, a multicenter RCT to examine the efficacy and safety of long-term mild hypothermia in severe TBI is planned in China (the LTH-1 trial).

The Eurotherm3235 [165] trial was a multicenter RCT assessing hypothermia as a second-tier treatment strategy along with standard medical management versus only medical management with an ICP threshold of 20 mm Hg. The study was stopped prematurely owing to safety concerns, but the results suggest that outcomes were worse with hypothermia than with standard care alone. Several questions have been raised about the trial concerning the timing of hypothermia in general practice and the treatment threshold of ICP used in the study. In a case control study, maintaining normothermia reduced the number of ICP spikes greater than 25 mm Hg, leading the authors to recommend fever avoidance in TBI patients [166]. Currently, the role of hypothermia in TBI is unclear.

Acute Stroke and the Role of Multimodal Monitoring

The use of MMM in acute stroke is far less common than in TBI. Still, the indications for MMM in acute ischemic/hemorrhagic stroke are like those discussed in the section on TBI above. The International Multidisciplinary Consensus Conference on Multimodality Monitoring has made recommendations regarding which non-TBI patients are suitable for ICP and CPP monitoring [167]:

1. Stroke patients with poor neurological exam either before or after decompressive hemicraniectomy.
2. Patients at risk for elevated intracranial pressure/hydrocephalus
3. Patients with supratentorial large hemispheric lesions or large infratentorial lesions

4. Patients with intraventricular hemorrhage with a GCS <8 (poor neurological exam) should be considered for an EVD and ICP and CPP monitoring
5. Patients with deep ischemic/hemorrhagic stroke (at risk for obstructive hydrocephalus) with imaging and clinical exam mismatch should be considered for MMM

Figure 8. CT images of the head showing diffuse subarachnoid hemorrhage and a frontal parenchymal hematoma with surrounding edema and midline shift. The tip of the EVD is seen in the left lateral ventricle on the axial imaging (Plate A). Coronal sections (Plates B and C) indicate the tip of the Licox probe placed into the normal brain parenchyma (Courtesy of N Badjatia, University of Maryland).

Location of Monitoring

There is no consensus on the ideal location of the MMM probe and the EVD site in the stroke population. The location of the probe should be in the area at highest risk of secondary injury. Thus, in stroke patients the best location is in the penumbra or perihematoma area [168] (Figure 8). However, in cases of severe unilateral damage or if the patient has already undergone a hemicraniectomy, the monitors are inserted into the contralateral areas near the side of lesion. There is also a concern for compartmentalization of elevated ICP in focal brain lesions at a deep or infratentorial location. Because of these limitations, the ICP numbers can be inaccurate and cerebral herniation can ensue without a rise in ICP [169].

ICP and CPP Monitoring in Stroke

When elevated ICP is a concern in management of stroke due to either intraventricular hemorrhage or cerebral edema, EVD is considered the gold standard for monitoring ICP [170, 171]. If intraparenchymal probes are used, the ICP sensor placed contralateral to the ischemic hemisphere can lead to an inaccurate estimation of ICP. Few, if any, studies have shown benefit with therapy guided by ICP monitoring in stroke care. American Heart Association/American Stroke Association guidelines recommend that patients with a GCS ≤ 8 , those with clinical evidence of transtentorial herniation, and those with significant intraventricular hemorrhage or hydrocephalus might be considered for ICP monitoring and

treatment. A CPP of 50 to 70 mm Hg has been recommended depending on the state of cerebral autoregulation [170, 171]. Regardless of the underlying physiologic differences in ICP elevation, maintaining proper CPP before initiating ICP-lowering treatments is of utmost importance. ICP monitoring can give us an understanding of autoregulation and cerebral physiology in stroke. Optimal CPP targets can be delineated for individual patients, and thus assist in pathophysiological goal-directed therapy. A single center using MMM consisting of ICP probe, PbtO₂ monitor, and cerebral microdialysis in intracerebral hemorrhage showed the risk of brain tissue hypoxia was higher with CPP <80 mm Hg than CPP >100 mm Hg [172]. In addition, survivors in the study had consistently lower elevations in their L/P ratio and PRx, showing intact cerebral autoregulation compared to those with fatal outcomes. One retrospective observational study utilizing ICP monitoring-based treatment in patients with stroke after decompressive hemicraniectomy showed effective treatment of ICP, but no studies have addressed differences in outcome with such treatment [173].

Cerebral Blood Flow in Stroke

TCDs can be used as a modality for estimating CBF. TCD is less accurate than CT angiography and MR angiography for steno-occlusive disease, with a sensitivity and specificity of 55% to 90% and 90% to 95%, respectively [170]. TCD usage is limited by the skills of the interpreter and the patient's vascular anatomy. Moreover, TCD is not applicable for posterior circulation strokes.

Cerebral Microdialysis in Stroke

In a small prospective clinical study of patients with malignant space-occupying infarction, monitoring showed a substantial increase in concentrations of glutamate and lactate and in the L/P ratio [174]. Overall, the data on cerebral microdialysis are limited in stroke. Data on PbtO₂ and SjvO₂ are obtained from the TBI studies, and very few studies have looked into their roles in the stroke population [175].

Monitoring of Cerebral Edema in Stroke

Malignant MCA stroke represents 2% to 8% of all hospitalized ischemic stroke cases, and MCA territory ischemic stroke accounts for 10% to 15% of patients hospitalized for stroke [176]. Clinical examination, cortical signs, NIH Stroke Scale, early pupillary abnormalities, and level of consciousness have been associated with malignant MCA and cerebral edema [176]. Neurological deterioration can occur within 72 to 96 hours, and sometimes up to day 10. In the cerebellar strokes, compression of brainstem structures and development of obstructive hydrocephalus will manifest as decline in consciousness with cranial nerve abnormalities [176]. CT is a readily available, safe first-line test that can be used to assess cerebral edema. Several CT findings have been shown to predict development of malignant edema and poor prognosis: hypodensity involving >50% MCA territory on CT within 6 hours, involvement of a third or more of the MCA, and a midline shift ≥ 5 mm within

2 days [176]. MRI is not as widely available and thus might not be suitable for every patient. The data on MRI to predict development of malignant edema suggest a superiority of MRI over CT. Two studies evaluating MRI within 6 hours found similar cutoffs for DWI volume, around 80 mL, to be highly predictive, with specificities of 50% to 95%, but sensitivities of 50% to 85%. A DWI volume cutoff of >145 mL for an MRI done in 14 hours achieved a 100% sensitivity and 94% specificity [176, 177].

Limitations of Multimodal Monitoring

MMM is limited in the following ways:

1. It is resource intensive and cumbersome.
2. It requires expertise in interpreting the complex data sets.
3. There is a lack of evidence on improved outcomes using this treatment strategy.
4. Data can be inaccurate depending on the limitations of the modalities and the factors affecting them.

Beyond the obvious challenges of expense, large number of human and technological resources needed, and requirement for expertise in interpreting data, some other problems are less obvious. Chief among these are acquisition, integration, and synchronization of MMM data. Electronic medical records have eased recordkeeping through automated data collection, and they provide more reliable documentation. Unfortunately, many monitors do not interface with electronic medical records. As a result, the data are being captured continuously, but recorded only intermittently. Clearly, further development of continuous data integration into electronic medical records with a user-friendly interface is required. This will help clinicians simultaneously visualize all of the data at any given time, interpret it, and then apply that knowledge to patient care.

CONCLUSION

The integration of MMM in the field of neurointensive care holds great promise for early recognition of worsening brain injury and improving the efficacy of treatment strategies. It is a powerful monitoring tool in cases where the neurologic exam is limited. MMM allows for individualized care rather than a general approach based on the collected continuous data. It helps us detect changes in cerebral physiologic and metabolic states. In addition, the effect of treatment strategy can be observed in real time and the approach can be tailored accordingly. Interpreting and acting on the different physiologic variables can be challenging and have several limitations. The accuracy of several probes and devices can vary based on several factors. Because clinical data on improved outcomes based on treatment guided by MMM are limited, further studies analyzing the application of MMM in improving patient outcomes are required.

Chapter 95

DECOMPRESSIVE CRANIECTOMY IN ISCHEMIC STROKE

Matthew Jaffa, DO, Carolyn A. Cronin, MD, PhD
and Barney J. Stern, MD*

Department of Neurology, University of Maryland School of Medicine,
Baltimore, MD, US

ABSTRACT

Few stroke syndromes have as high a risk of mortality or severe disability as does the “malignant” middle cerebral artery infarction seen in the setting of large artery occlusions. Malignant stroke syndromes are relatively rare; however, when present they are associated with a close to 80% mortality rate. The management of these patients is controversial and presents a major challenge for the neurologists, neurosurgeons, and neurointensivists caring for them. Many studies have assessed the benefits and risks of decompressive craniotomy versus optimal medical management, with the goal of improving not only survival but also survival with good functional outcomes. The conclusions of these studies remain mixed, and practice patterns vary widely. We review the landmark trials of decompressive surgery in ischemic stroke as well as the pooled analyses and those addressing quality of life to improve our understanding of this complicated syndrome in which the optimal management strategy may vary depending on a patient’s values and preferences.

Keywords: malignant stroke, decompressive craniotomy, large artery occlusion, quality of life, functional outcomes

INTRODUCTION

Stroke is defined as the sudden onset of neurologic disability caused by neuronal death due to blockage or severely reduced blood flow or hemorrhage within the brain parenchyma. Currently, stroke is the world's second leading cause of mortality and third for disability [1]. In the United States, stroke is now the fifth leading cause of death, is one of the top causes of long-term disability, and costs the nation nearly 33 billion dollars annually [1]. Larger territories of parenchymal damage typically equate to higher levels of morbidity and mortality. In this chapter we discuss the definition of malignant cerebral infarction and the role of decompressive craniectomy in the treatment of stroke and prevention of both morbidity and mortality.

In the United States, more than 80% of strokes are ischemic. Ischemic infarctions result from three main mechanisms: thrombosis, embolism, and cerebral hypoperfusion. Thrombosis typically is the result of disease of the arterial wall such as atherosclerotic plaque, whereas embolism is the result of vessel occlusion by blood clot or other material dislodged from a more proximal site such as a larger diameter vessel or a chamber of the heart. Thrombosis and embolism may lead to occlusion of vessels anywhere from the more proximal internal carotid artery (ICA) to the most distal branches of the intracerebral vasculature. Branches of the middle cerebral artery (MCA) are denoted with a number for each more distal branching point from M1 to M4. Each succession of branching vessels leads ultimately to an individual area of brain tissue perfused by the most distal vessels. Therefore, the more proximal a site of blockage is, the greater the amount of the parenchyma at risk for infarction. Systemic hypotension can lead to a more global process of damage with the greatest source of ischemic damage being in the areas of distal vessel overlap known as the "watershed zones" or "border zones" between the anterior cerebral artery (ACA), MCA, and posterior cerebral artery (PCA).

While a strategically placed stroke in the cerebral hemispheres or brainstem may lead to profound neurologic disability including loss of language abilities, alteration in personality, visual loss, and hemiplegia, few infarctions are associated with as high a likelihood of mortality or severe morbidity as are large artery occlusions that result in an infarction involving a large volume of brain. The "malignant" MCA syndrome is one of these infarctions, and typically is the result of occlusion of the distal ICA or proximal MCA [2]. Hacke introduced the term "malignant MCA syndrome" in 1996. It describes the small subset of stroke victims with severe hemiparesis and sensory loss, horizontal gaze deviation, and global aphasia (when the dominant hemisphere is involved) that progress to deterioration of their mental and respiratory status within the first 24 to 48 hours of symptom onset [2-5]. Death from cerebral edema and herniation leading to compression of the brainstem commonly occurs in the first 2 to 5 days following infarction [2, 3]. The malignant MCA syndrome is associated with a greater than 80% mortality [2, 6]. Fortunately, these infarctions are relatively rare, encountered in only about 10% of all patients with ischemic strokes [4]. Each year approximately 70,000 patients are at risk for the malignant MCA syndrome in the United States alone.

Predicting which patients will develop such severe stroke syndromes and their impending rates of death and disability is a source of great interest. Higher National Institutes of Health Stroke Scale (NIHSS) scores have a high sensitivity (96%) but a low specificity (72%) for

those patients with scores greater than 19 in the prediction of the development of malignant stroke syndromes, while identification on magnetic resonance angiography of an internal carotid artery “T-lesion” has a lower sensitivity of 64% but greater specificity of 85%, making neither a perfect predictor [7]. Imaging findings have been found to have the strongest predictive value. Early work by von Kummer et al. showed that early computed tomography (CT) hypodensity representing greater than 50% of the MCA territory within 5 hours of stroke onset was predictive of fatal outcomes in 85% of cases [8]. Later magnetic resonance imaging studies showed a 100% sensitivity and 94% specificity for predicting malignant MCA syndrome in patients with a diffusion-weighted imaging lesion greater than 145 mL up to 14 hours after symptom onset [3, 9]. Thomalla et al. demonstrated that more rapid completion of magnetic resonance imaging within 6 hours could be predictive of malignant MCA syndrome with changes in apparent diffusion coefficient volume greater than 82 mL [3, 7].

ACUTE MANAGEMENT OF ISCHEMIC STROKE

Time is of the essence in the acute management of ischemic infarction. Longer duration of ischemia leads to increasing neuronal death and likelihood of permanent damage. Treatment with intravenous tissue plasminogen activator (IV tPA) within 3 hours from the time of symptom onset has been shown to reduce morbidity at 3 months compared to placebo in the National Institute of Neurological Disorders and Stroke (NINDS) trial and then later with an extension of the time frame to 4.5 hours in the European Cooperative Acute Stroke Study 3 (ECASS III) [10, 11]. Data consistently demonstrate that for every 15-minute shortening in time to treatment there is a mortality and morbidity benefit [12]. The time standard of care for reperfusion treatment has been expanding since the positive results of trials for endovascular therapy were published beginning with the Multicenter Randomized Clinical Trial of Endovascular Treatment for Acute Ischemic Stroke in the Netherlands (MR CLEAN) [13] in January 2015. With the completion of additional trials, namely, Endovascular Treatment for Small Core and Anterior Circulation Proximal Occlusion with Emphasis on Minimizing CT to Recanalization Times (ESCAPE) [14], Extending the Time for Thrombolysis in Emergency Neurological Deficits - Intra-Arterial (EXTEND-IA) [15], Solitaire with the Intention for Thrombectomy as Primary Endovascular Treatment (SWIFT-PRIME) [16], and Randomized Trial of Revascularization with Solitaire FR Device versus Best Medical Therapy in the Treatment of Acute Stroke Due to Anterior Circulation Large Vessel Occlusion Presenting within Eight Hours of Symptom Onset (REVASCAT) [17], the American Heart Association/American Stroke Association (AHA/ASA) updated its acute stroke management guidelines to include use of endovascular therapy with stent retrievers for large artery occlusions (i.e., ICA and M1) for patients up to 6 hours from their last known normal time [18].

Ultimately, the goal of these interventions is recanalization of the occluded vessel to restore blood flow to distal ischemic tissue. Rha and Savers’ meta-analysis of 53 studies examining recanalization reported that recanalization was achieved 24.1% of the time spontaneously, 46.2% with IV tPA, and 83.6% with mechanical thrombectomy [19]. Recanalization is determined by several factors, the most important of which are length and

location of the thrombus. In MCA thrombosis there is a high likelihood of recanalization following IV tPA for clots less than 5 mm in length as compared to a less than 1% chance for clots longer than 8 mm [20]. Recanalization of the ICA has the lowest success rate at 49% across all methodologies, with IV thrombolysis yielding the lowest rate of 13% [19]. Even with the success of early recanalization, studies have shown that the final infarct volume, not recanalization, is what drives outcomes [21, 22]. Thus, mitigation of the morbidity and mortality associated with these infarctions depends not only on recanalization success but also on the subsequent management of patients at high risk for malignant cerebral infarctions.

STUDIES OF DECOMPRESSIVE CRANIECTOMY

After the emergent management and stabilization of acute stroke patients, including patients treated with IV tPA or endovascular recanalization, the patient is typically observed in a critical care or stroke unit. Patients thought to be at risk for development of the malignant MCA syndrome are usually observed in a critical care unit.

The studies discussed here were all designed to answer the question of the role of decompressive craniectomy in the treatment of malignant cerebral edema following ischemic infarction. Trials looked at the outcomes of mortality as well as modified Rankin Scale (mRS) scores [23] to quantify long-term disability, as described in Table 1. On this non-linear scale, 0 indicates no symptoms while 6 indicates death. The differences between scores of 3 and 4 are related to the ability to ambulate and attend to one’s bodily needs without assistance. These scores, which were found to have a significant relationship with discharge to institutional care in the large Nationwide Inpatient Sample data pool, are an active area of debate and discussion about how to judge the impact of the intervention [24, 25]. All trials were stopped early because of poor/slow enrollment and the desire to pool data for meta-analyses. These three trials form the basis of all the meta-analyses that will be reviewed later.

Table 1. Modified Rankin Scale scoring description

Modified Rankin Scale (MRS)
0 No symptoms
1 No significant disability, despite symptoms; able to perform all usual duties and activities
2 Slight disability; unable to perform all previous activities but able to look after own affairs without assistance
3 Moderate disability; requires some help, but able to walk without assistance
4 Moderately severe disability; unable to walk without assistance and unable to attend to own bodily needs without assistance
5 Severe disability; bedridden, incontinent, and requires constant nursing care and attention
6 Death

DECIMAL [26]

The decompressive craniectomy in malignant MCA infarction (DECIMAL) trial was completed at 13 stroke centers in France from December 2001 through November 2005. The trial enrolled patients between the ages of 18 and 55 within 24 hours of an acute ischemic stroke that met criteria suggestive of the patient's being at high risk for a malignant MCA syndrome. Patients were enrolled if they had an NIHSS score of greater than 16, CT of the head with hypodensity in more than 50% of the MCA territory, and a DWI stroke volume of greater than 145 mL. Thirty-eight patients were enrolled and randomized to receive either decompressive craniectomy within 6 hours of randomization or 30 hours following symptom onset versus maximal medical therapy which included preventing hyperthermia or hyperglycemia, maintaining the head of the bed to an elevation greater than 30°, intravenous hydration, and the use of intravenous mannitol in patients with rapidly progressing symptoms due to edema.

The results of this first study demonstrated a life-saving effect with respect to craniectomy. Those in the surgical arm had an almost 53% absolute reduction in death. Follow-up for patients was reported at 6 months and 1 year after enrollment. At both time points, a greater proportion of patients had a mRS of less than or equal to 3 in the surgical treatment group than the medical group. At 6 months the difference was 25% versus 5.6%, and at 1 year those percentages increased to 50% and 22.2% for surgical and medical therapy, respectively, as depicted in Figure 1; the P values for these data points were not statistically significant. When using mRS of less than or equal to 4 as the outcome measure, the difference at 1 year increased to 75% in the surgical arm versus 22.2% for the medical arm ($P = 0.0029$).

Figure 1. DECIMAL trial patient outcomes (Reprinted from *Stroke*, 38(9), Vahedi et al. Sequential-design, multicenter, randomized, controlled trial of early decompressive craniectomy in malignant middle cerebral artery infarction (DECIMAL Trial), Pg 2511, 2007, with permission from Elsevier).

The DECIMAL trial brought to light the idea that while survival was significantly improved by surgical intervention, the two treatment arms had no statistically significant difference in survivors with good outcomes (mRS less than or equal to 3). However, because the trial was stopped early, it likely did not have power to show a statistically significant difference.

DESTINY [27]

This trial of decompressive surgery for the treatment of malignant infarction in the MCA territory enrolled 32 patients across six study sites in Germany from February 2004 through October 2005. Inclusion criteria for this study included subjects aged 18–60 years, NIHSS score >18 in patients with non-dominant hemisphere infarcts and >20 when in the dominant hemisphere, and CT imaging findings demonstrating infarction of greater than two thirds of the MCA territory including part of the basal ganglia. Patients were randomized either to conservative therapy, which allowed for the use of osmotic therapy for any signs of increasing edema, intubation and hyperventilation, sedation, ICP monitoring, and maintenance of normothermia and euglycemia, or to surgical decompression within 36 hours of symptom onset.

Figure 2. DESTINY trial patient outcomes (Reprinted from Stroke, 38(9), Juttler et al. Decompressive Surgery for the Treatment of Malignant Infarction of the Middle Cerebral Artery (DESTINY): a randomized, controlled trial, Pg 2523, 2007, with permission from Elsevier).

Randomization groups were fairly evenly matched, though it was noted that because of more patients with dominant hemisphere strokes in the control group, the NIHSS score was modestly higher at time of entry to the study in this group. Patients were predominantly screened and treated at one center. End points for the study included the 30-day survival reported as 88% in the surgical arm versus 47% in the conservatively managed group. The trial was designed to evaluate not only the mortality associated with malignant infarctions but also the functional outcomes at 6 months and 1 year, as represented in Figure 2. Again, the study results were dichotomized at a mRS score of less than or equal to 3, with 47% of

patients achieving this in the surgical group and only 27% in those conservatively managed. These results again trended positive but were not statistically significant, whereas when the good outcomes score is expanded to mRS less than or equal to 4 there is a significant improvement based on surgical intervention.

HAMLET [24, 28]

The Hemicraniectomy After MCA infarction with Life threatening Edema Trial (HAMLET) was completed at six centers in the Netherlands from November 2002 through October of 2007 and enrolled 64 patients. Patients aged 18 to 60 years were randomized to surgical decompression or medical therapy within 96 hours of symptom onset. The inclusion time of up to 96 hours from symptom onset was a major difference between HAMLET and the other trials (24 hours for DECIMAL and 36 hours for DESTINY). Inclusion criteria included a NIHSS score of >16 in right hemispheric stroke patients and >21 for left hemispheric stroke patients as well as hypodensity covering at least two thirds of the MCA territory on CT imaging.

Figure 3. HAMLET trial patient outcomes (1 year) (Reprinted from The Lancet, 8(4), Hofmeijer et al. Surgical decompression for space-occupying cerebral infarction (the Hemicraniectomy After Middle Cerebral Artery infarction with Life-threatening Edema Trial [HAMLET]): a multicentre, open, randomised trial, Pg 329, 2009, with permission from Elsevier).

In this study, the only endpoint that was shown to have a significant reduction with hemicraniectomy was the likelihood of death, with an absolute risk reduction of 38%. The primary outcome of mRS dichotomized between 0–3 and 4–6 at 1 year had an absolute risk reduction (ARR) of 0%, though when extended to 0–4 versus 5–6 there was a trend toward benefit with surgical decompression and an ARR of 19%, as depicted in Figure 3.

Meta-Analyses

DECIMAL and DESTINY were halted prematurely in 2006 to combine the data for a meta-analysis. Each of the three trials had a similar protocol and outcome parameters allowing for relative ease of pooling patient data. Given the differences in eligibility criteria between studies, subjects were only included in the combined analysis with ages between 18 and 60, an NIHSS score >15, and a CT scan demonstrating infarction of at least 50% of the MCA territory or DWI infarct volume >145 mL. From these three studies, 93 patients were included who had been randomized within 45 hours of symptom onset [29]. In this data set, a

primary outcome of mRS 0–4 was chosen to define favorable outcome, with secondary analyses using mortality at 1 year and favorable outcome of mRS 0–3.

The pooled analysis demonstrated the positive effects of decompressive craniectomy with an ARR of 51.2% when comparing patients with mRS 0–4 versus 5–6 at 12 months [29]. Craniectomy reduced rates of death from 71% to 21.5%, as seen in Figure 4, essentially inverting the historical mortality rate for malignant MCA infarctions. In addition, when dichotomized for mRS 0–3 versus 4–6 there was still a significant ARR of 22.7% ($P = 0.014$). These data suggested that the previous concern that decompressive craniectomy improves survival while leaving the majority of patients in a severely debilitated state (i.e., mRS = 5) was false and that, in fact, the likelihood of this was nearly unchanged.

Figure 4. Pooled Analysis of DECIMAL, DESTINY, and HAMLET (1 year patient outcomes) (Reprinted from *The Lancet*, 6(3), Vahedi et al. Early decompressive surgery in malignant infarction of the middle cerebral artery: a pooled analysis of three randomised controlled trials, Pg 218, 2007, with permission from Elsevier).

In the years since this first meta-analysis and the results of the individual trials were published (2007–2009), several additional groups have looked at the data for hemicraniectomy in malignant cerebral edema related to MCA infarction. These studies again highlight the long debated question of the utility of surgical treatment in malignant stroke when the risk of severe disability is weighed against death and how severe disability should be defined.

Back et al. reviewed six studies in 2015 that included the three previously described studies as well as three more recently completed studies [30]. DESTINY2 [31], the follow-up to DESTINY, examined the effect of surgical decompression in patients older than 61 years. The Hemicraniectomy and Durotomy Upon Deterioration From Infarction-Related Swelling Trial (HeADDFIRST) [32] standardized the medical therapy provided to patients in neurologic intensive care units, including waiting until clinical deterioration before proceeding to decompression. Zhao et al. studied patients randomized up to the age of 80 in China [33]. To compare the 317 patients from these six studies, the researchers utilized odds ratios (OR) to assess the likelihood of each individual mRS outcome with respect to medical management versus surgery. They found that, as in each individual study, an mRS of 6 (death) was significantly reduced with surgical decompression with an OR = 0.19 and 0.17 at 6 and 12 months, respectively [30]. While the number of patients with mRS scores of 3 and 5 were increased at 6 and 12 months in the patients randomized to surgery, these did not reach statistical significance. The authors did find a significant increase in patients with mRS of 2 at

12 months (OR = 4.51). However, at both follow-up time points, surgical patients also had a statistically significantly higher likelihood of having an mRS of 4 with OR = 3.29 and 4.43 for 6 and 12 months, respectively [30].

Table 2. Likelihood of different outcomes based on meta-analysis of 6 trials [35]

	All patients		Patients >60 years	
	ARI	NNT	ARI	NNT
Excellent Functional Outcome (mRS 0-2)	6.6%	15.2	*	n/a
Favorable Outcome (mRS 0-3)	15.0%	6.7	4.0%	25.0
Unfavorable Functional Outcome (mRS 4-5)	29.5%	3.4	32.5%	3.1
*No patients > 60 with mRS 0-2				

ARI = Absolute Risk Increase; NNT = Number Needed to Treat.

Two additional meta-analyses have been performed by Yang et al. and Streib et al. utilizing five of the same six studies, but replacing the HeADDFIRST data with that from the preliminary results of a Croatian study by Slezins et al. [34, 35]. In the review by Yang et al. mortality was significantly decreased in the setting of early craniectomy (OR = 0.19, 95% confidence interval [CI]: 0.12–0.30; $P < 0.00001$), though the number of patients surviving with an mRS outcome of 4–5 was not statistically different for craniectomy or best medical therapy (pooled OR = 1.71, 95% CI: 0.78–3.74; $P = 0.18$) [34]. Both demonstrated that regardless of age the results were consistent, although in patients older than age 60 the likelihood of achieving survival with an mRS of less than 3 was zero regardless of treatment arm, and only 7% had a score of 3 after surgery compared to 3% in the medical arm [35]. In their primary analysis, Streib et al.'s meta-analysis evaluated the absolute risk increase for undergoing early craniectomy and therefore number needed to treat to meet defined functional outcome categories. Table 2 shows likely outcomes based on data from Streib et al. [35].

More recently, Dasenbrock et al. analyzed data from the National Inpatient Sample database to assess the predictors and association of time to decompressive craniectomy with outcomes. The review of approximately 1300 inpatient admissions evaluated the outcomes of discharge to institutional care (i.e., nursing facility, extended care facility, or hospice, but excluding rehabilitation or other acute care facility) and poor outcome (defined by death, tracheostomy and gastrostomy, or discharge to institutional care) based on time to surgery both on a continuous scale as well as dichotomously. Greater delay in surgery was associated with greater likelihood of discharge to institutional care with an OR = 1.17 (95% CI: 1.05–1.31; $P = 0.005$) and poor outcome with an OR = 1.12 (95% CI: 1.02–1.23; $P = 0.02$) (25). In the dichotomous analysis there was no difference in outcomes within 24 or 48 hours but increased odds of poor outcome after 72 hours (OR = 1.52, 95% CI: 1.07–2.16; $P = 0.02$). Discussion of the predictors for surgery concluded that craniectomy before herniation might be a more important factor, especially in patients who do not have significant decompensation prior to 48 hours from stroke onset [25]. Of course, this study also must be looked at with a cautious eye as the data collected were based on diagnostic coding as opposed to the more traditionally utilized data including NIHSS score, premorbid mRS, and distribution or size of infarct area. Still, the most interesting finding was that practices for timing of craniectomy did not seem to have any relationship to the year of operation as one might predict if the

previously discussed clinical trial data were being utilized as recommendations for changing clinical practice [25].

POSTERIOR CIRCULATION INFARCTIONS AND DECOMPRESSION

While a great deal of research has been directed toward determining the benefits of decompressive surgery in malignant MCA infarctions, there are limited data regarding aggressive treatment of patients with edema from cerebellar infarctions. Possibly more menacing than even large hemispheric strokes, those in the posterior circulation and affecting the cerebellum can lead to life-threatening upward herniation with only small increases in swelling due to the limited space in the posterior fossa. Suboccipital decompression (SDC) has been performed in the setting of brainstem compression and obstructive hydrocephalus as a life-saving therapy. Unfortunately, there have been no randomized controlled studies to suggest the actual benefit of this procedure nor research into which patients would likely benefit the most.

From March of 2007 until September of 2015, records of 1162 patients admitted to one of five hospitals in Korea for cerebellar infarction were reviewed and selected for a case-control study of SDC versus medical management. Twenty-eight patients who had undergone SDC and 56 who had not were reviewed and assessed using multiple logistic regression propensity score matching based on having had a cerebellar infarction volume ratio between 25% and 33% with a Glasgow Coma Scale score greater than or equal to 9 and no clinical deterioration prior to 72 hours from symptom onset. Insertion of an external ventricular device for cerebrospinal fluid drainage as treatment for hydrocephalus was performed in patients with findings of significant hydrocephalus, including 50% of those patients who underwent preventive SDC and 90.6% of those requiring emergent intervention [36]. At follow-up 1 year after the infarction, 66.7% of those receiving SDC had a favorable outcome ($P = 0.030$), defined as mRS of 0–2, versus 51% of those who had not undergone SDC ($P = 0.030$) [36]. The results from this case-control series indicate that *preventive* SDC prior to signs of brainstem compression or obstructive hydrocephalus in patients with an infarct volume ratio of 0.25–0.33 may be beneficial.

Even with the results of this study, there is still a great need for further research into the characteristics of those patients who have suffered a cerebellar infarction and will have overwhelming cerebellar edema leading to increased morbidity and mortality associated with brainstem compression or infarction. While not the main focus of this chapter, it certainly is an important area for future research.

QUALITY OF LIFE

Ultimately, each of these individual studies and meta-analyses demonstrates that while neurosurgical intervention has a clear survival benefit in nearly all patients with malignant MCA syndrome, the evidence of a beneficial difference in morbidity depends on the authors' definition of "good" outcome. Similar to the opinions espoused in the discussions of the more recent meta-analyses, we feel very strongly that a patient's individual beliefs and goals of

care need to be weighed when deciding to move forward with surgical decompression in the setting of malignant edema. The data suggest a trend toward an increased representation of patients with outcomes that would allow for a life at home, albeit many will require significant help from family members. Review of those same studies shows a statistically significant increase in the number of patients who survive with an mRS of 4 that would almost certainly mean a life relegated to living with dependence on others for all of their needs.

Quality of life (QoL) data were collected in most of these trials either prospectively or retrospectively and reveal that relatively few patients or family members regret the decision to undergo surgery despite the ultimate level of dependency [26, 37]. A review of seventeen studies of craniectomy in malignant edema reported outcomes for QoL with data available for six of those trials that looked at scores of overall QoL. Patient QoL measures were in a range of 60% to 67% (an outlier in the DESTINY study of 46% was noted) as compared to best possible QoL [38]. Depression among patients has been reported as mild to moderate in almost 50% of survivors and severe in 15% [38]. While these values may appear to be relatively high, in view of the fact that patients with more severe disability were also included in these analyses, it suggests that patient perception of disability may change or be different at baseline than previously believed [39]. This divide in the acceptability of outcome can be demonstrated when neurologists, neurointensivists, and neurosurgeons were polled: only 38% believed an mRS of 4 to be a favorable outcome [40]. Do patients simply adapt to a disability and life they never before would have accepted?

The answer to that question is exceedingly complex and requires an intimate knowledge of the patient's previous insights and life goals. As would seem obvious, most of the patients who present with a massive ischemic infarct were not expecting or planning for this abrupt change in their lives. Further complicating the situation is that many individuals have neither had a conversation with their legally authorized representatives nor documented their wishes in an advance directive. Even if a person had indicated their general wishes, the circumstances surrounding malignant brain infarction are unique enough that patients and family will need to extrapolate from their prior constructs to the specifics of their current medical condition. Moreover, the physicians caring for them did not have a prior relationship with the patient or their loved ones, though their primary care providers might be able to provide insight into the patient's wishes. It is our practice to look at each individual patient and discuss with the family and patient, if possible, the wide array of outcomes that may occur in the setting of potential malignant brain infarction. This conversation unfortunately relies on a great many unknowns and can be easily directed by the framework in which it is presented.

OPINIONS FROM EXPERIENCE

Reviewing the data from these trials suggests that in patients under age 60 decompressive craniectomy has both mortality and morbidity benefits, though the morbidity must be carefully defined as including the possibility of need for around the clock care. While none of the previously discussed studies analyzed data dichotomized by early versus later surgery, a study from China looked at "ultra-early" surgical decompression in those with an NIHSS

score greater than 20 and imaging suggestive of impending herniation syndromes at an inflection point of 6 hours. This study found a statistically significant reduction in mortality in surgically treated patients as well as compromised function as based on Glasgow Coma Outcome scores, with no increase in surgical complications if operated on before or after 6 hours from time of stroke onset [41]. Thus, we believe, pending new research findings, that patients requiring hemicraniectomy should be treated within 48 hours of symptom onset, and not after the patient begins to demonstrate findings of progression from malignant edema. That being said, we appreciate that the glyburide treatment studies published to date, GAMES and GAMES-RP, recommended decompressive craniotomy only after the patient exhibited symptoms and signs of deterioration (defined as Glasgow Coma Scale score ≤ 8 , increase of ≥ 1 on item 1a of the NIHSS score, new pupillary abnormalities, or less brisk response to pain) to have time to determine the efficacy of medical therapy alone prior to surgery [42, 43].

In our own experience, we find hemicraniectomy to be infrequently advised within an early timeframe in the hope that optimal medical therapy will allow some patients with large MCA territory infarcts to “sneak by” without surgery. Often, surgical options are explored only after it is thought that medical optimization has taken the patient as far as it can and by this point there are signs of impending or active herniation (i.e., decrease in consciousness, pupillary changes, or evidence of vascular compromise of the non-infarcted hemisphere). Does holding off on surgery lead to irreversible damage that ultimately leaves the patient with increased disability and a higher likelihood of being classified as an mRS 4 instead of a 3? Might earlier surgery spare brain tissue at risk for infarction or anatomical distortion as suggested by observations in study patients treated with glyburide for prevention of brain swelling as well as laboratory observations in rats [44-46]?

Figure 5: Algorithm for Hemicraniectomy Decision in Malignant Cerebral Infarction as developed by Streib et al. [35] (Reprinted from Neurology Clinical Practice, 6(5), Streib et al, Early decompressive craniectomy for malignant cerebral infarction: Meta-analysis and clinical decision algorithm, Pg 440, 2016, with permission from Elsevier).

There is an important role for early patient and family (or legally authorized representative) discussions to be conducted for patients at high risk for malignant infarction. To determine the most appropriate direction of care, a good understanding is necessary of what a patient may consider to be a reasonable outcome and in turn the care provider should describe the most objective outcome probabilities based on the data available. Streib et al. created a clinical decision algorithm that dichotomizes decisions based on whether a patient would find a life dependent on others acceptable. In their estimations for patients under the age of 60, when an mRS of 3 is considered acceptable QoL, there is a 35% likelihood of poor QoL with only a 43% likelihood of good QoL, whereas when an mRS of 4 is defined as acceptable, then those likelihoods are 9% and 69%, respectively [35]. For patients older than age 60, the likelihood of good outcomes is more restricted, as represented in Figure 5.

FUTURE DIRECTIONS

The meta-analyses discussed here are not the final statement for the care of patients with malignant MCA infarctions. The protocols demonstrate regional and individual physician treatment preferences, especially for medical management. In fact, there are now American Heart Association/American Stroke Association guidelines for medical management for patients at risk for severe brain swelling following stroke, though many of the interventions have not been critically evaluated [47].

Further research on and discussion of the ethics of decompressive surgery should acknowledge that decisions are often made within the context of time constraints and the stress of critical illness and are deserving of further exploration. The collaboration of stroke neurologists, neurointensivists, neurosurgeons, patients, and their families is paramount to the improvement in outcomes for patients with malignant edema from ischemic infarction. Ideally, an institutional protocol for directing conversation between disciplines should be developed and implemented, thus creating a pathway for this decision making process.

CONCLUSION

Large territory, “malignant,” ischemic infarcts are associated with exceedingly high morbidity and mortality. In the past 20 years, multiple studies [24, 26, 27, 29, 32, 33] have been undertaken to establish the benefits of surgical decompressive craniotomy. Results have been mixed demonstrating a paradoxical improvement in mortality and good outcomes, but at the cost of an increase in poor outcomes. Currently, there is no consensus with regard to the timing of surgical intervention and which patients will benefit. Review of the available literature [25, 29, 30, 34, 35, 37] suggests that surgery continues to be an individually applied treatment, though likely with the greatest positive impact on patients under the age of 60 and those who have decompressive surgery within the first 48 hours from symptom onset. Continued collaboration between neurologists, neurosurgeons, neurointensivists, and patients and their families to identify the patients whose clinical presentation and goals of care align with intensive therapy, including early surgery, is vital to providing the best chance for each patient to achieve a desirable outcome. Finally, should new brain anti-swelling drugs become

available, the concepts outlined will need to be re-examined within a new management context.

ABSTRACT

Upper extremity (UE) rehabilitation is of utmost importance to the achievement of full inclusion and functional independence. Traditionally presented as well as technology-based therapeutic interventions have produced measurable changes in motor function and motor control but fall short of major reductions in disability. Animal models of stroke suggest that the first two weeks to one month post stroke may be a critical time period of increased brain plasticity. This study shows the feasibility of adding one hour of intensive robotic/virtual reality (VR) therapy to on-going rehabilitation in the acute phase of recovery post-stroke. All five of the subjects made substantial improvements in Upper Extremity Fugl-Meyer Assessment (UEFMA) scores (mean improvement = 6 points (SD = 2)) as well as improvements in Wolf Motor Function Test (WMFT) time (average decrease = 41% (SD = 35) after training with more consistent changes in the proximal

arm portions of the WMFT and the UEFMA as well as in upper arm kinematics. Maps of cortical excitability indicate an increase in both the area of activation and the volume of activation of the first dorsal interosseous (FDI) muscle after a two-week training period.

Keywords: stroke, rehabilitation, upper extremity, arm, hand, virtual reality

INTRODUCTION

People post-stroke exhibit paresis of the upper and lower extremities. When a person with paresis uses their upper extremity (UE) for purposeful movement, the paretic movements differ from normal movements in that they are slower, less accurate, have delayed or reduced force, and are uncoordinated in terms of magnitude and timing of the movement. Upper extremity rehabilitation is of utmost importance to the achievement of full inclusion and functional independence. Plasticity-mediated therapies have evolved from the concepts of adaptive activity-based neuroplasticity, task-oriented motor training and the need for high doses of repetitive practice. One approach to plasticity-based therapy – the combination of virtual reality and rehabilitation robotics – has offered new promise for enhanced outcomes for upper extremity rehabilitation. The literature shows a progression of articles, from feasibility studies, to small clinical trials and a recent Cochrane review suggesting the potential benefits of using virtual reality for rehabilitation. However, to date, the best efforts of groups studying technology-based therapeutic interventions have produced measurable changes in motor function and motor control, but fall short of major reductions in disability.

The prevalence of studies in people with chronic stroke, or Cerebral Vascular Accident (CVA), stands in contrast to animal models of stroke that suggest that there may be a critical time period of increased brain plasticity (1). During the first month post stroke the peri-infarct cortex regains responsiveness to cortical afferents with accompanying increased dendritic spine morphogenesis and axonal sprouting (2). Rats trained with daily sessions of reaching showed significant gains in forearm reaching ability when the training was started 5 or 14 days post infarct but not 30 days post infarct (1). The important question these studies raise is whether early intensive training might be more effective.

To date only three studies have focused on task-based upper extremity interventions in persons in the acute period post-stroke. A study by da Silva-Cameriao of persons less than thirty days after CVA, identified faster recovery of upper extremity motor function in patients performing virtually simulated rehabilitation activities (VSRA) for twenty minutes in addition to a standard inpatient rehabilitation program (SIRP) when compared to controls who performed a dose matched increase in activity beyond their SIRP (3). This finding is important because it establishes the feasibility of using VSRA in addition to an SIRP very early after a CVA. This study also suggests that VSRA might have an effect during the acute stages of stroke. The second study using a more traditionally presented intervention (CIMT) did not demonstrate additive benefits (4).

This study was designed to test the feasibility of training patients between one and eight weeks after a CVA using our intensive robotically facilitated, virtually simulated UE motor intervention (5). The intervention utilizes several innovative, technology based approaches such as simulated activities that adapt in difficulty based on patient performance, robotic antigravity support, trajectory shaping as needed, and the virtual magnification of small active

finger movements into meaningful virtual activities. We hypothesized that this intense, targeted intervention would be tolerated well by persons in the first weeks following a stroke that were participating in inpatient or outpatient rehabilitation concurrently. In addition a battery of clinical, kinematic and neurophysiologic testing was performed to provide data to establish sample sizes for controlled studies of alternative treatments which will occur in the future.

METHODS

We performed feasibility testing with a single group of seven persons. Subjects were recruited from a consecutive sample of patients from the in-patient department of a suburban hospital. After initial screening by the department's physician, a physical therapist screened subjects based on the following criteria. Inclusion: (i) within 2 months post stroke; (ii) between the ages of 30 and 80; (iii) partial active shoulder flexion, or abduction, elbow extension and wrist extension against gravity; and (iv) trace extension at the fingers (detected visually) that can be reproduced several times in a minute. Exclusion: (i) severe spasticity (Modified Ashworth (4); (ii) cognitive deficits rendering them unable to follow three step commands or attend to task for at least ten minutes; (iii) hemi-spatial neglect rendering them unable to interact with an entire twenty four inch screen; (iv) proprioceptive loss that rendered a potential subject unable to interact with a virtual environment without looking at their hand; and (v) unstable blood pressure and oxygen saturation responses to activity. A separate screening and consent process for the motor mapping evaluation using transcranial magnetic stimulation was conducted.

System

The NJIT RAVR System consists of an instrumented glove combined with the Haptic Master (Moog-NCS, The Netherlands), a 3 degrees of freedom, admittance controlled (force controlled) robot. Three more degrees of freedom (yaw, pitch and roll) are added to the arm by using a gimbal for pronation/supination (roll). A three-dimensional force sensor measures the external force exerted by the user on the robot. In addition, the velocity and position of the robot's endpoint are measured allowing the robotic arm to act as an interface between the participants and the virtual environments (described below). The Haptic Master allows one to program the robot to produce haptic effects, such as spring, damper and constant force and to create haptic objects like blocks, cylinders and spheres as well as walls, floors, ramps and complex surfaces. The users interface with the Haptic Master via a forearm trough that extends through the gimbal, allowing for partial support of the weight of the arm as needed, while maintaining the ability to produce and measure pronation and supination movement. The NJIT TrackGlove System consists of a CyberGlove™ (Immersion, USA), an instrumented glove for finger angle tracking, and a TrackStar™ three-dimensional magnetic tracking system (Ascension Technologies).

Simulations

We have developed a suite of simulations for training shoulder, elbow, wrist and finger movements using the Virtools software package (Dassault Systemes). See Table 1 for descriptions of simulations that were used and the movement constructs they target.

Training protocol

To explore the feasibility of adding an hour of intense upper extremity activity to a standardized in-patient rehabilitation program, subjects received 60 minutes of training using the robot and the virtual reality gaming simulations in addition to their on-going in/out-patient physical, occupational and speech therapy for 5 days/week for two weeks.

Outcome measures

We examined the ability of our clinical, kinematic and neurophysiological measures to document changes in motor performance and neural control in persons having had their stroke less than thirty days prior to testing and training.

Clinical assessment. Subjects were tested one day prior to training (pre-test) and one day after training (post-test). A physical therapist performed the Wolf Motor Assessment Function Test (6) and the upper extremity portion of the Fugl-Meyer Assessment (7).

Kinematic assessment. Pre/Post kinematic measures included changes in distal kinematics, proximal kinematics and force. All measures were collected with the patients seated with their trunks supported and their hands resting on a table. Performance for all tracing tasks was measured following a single familiarization trial which was not scored.

Finger angles were collected using a Cyberglove™ (Immersion, USA). Finger range of motion was measured as the difference between all of the joint angles with the fingers in a relaxed/flexed position and the joint angles of all of the fingers actively extending the fingers as much as possible. Larger differences indicated better active finger extension range of motion. Finger Trace is the ability to modulate active finger extension and flexion between zero and eighty percent of max extension, measured by having the subject flex and extend their fingers to control a cursor tracking a sine function wave (period = 0.15 Hz, duration of 1 cycle $\approx$ 6 seconds). Lower root mean square error values indicate better performance.

Shoulder and elbow coordination was measured by having the subject trace a figure of eight (diameter of each circle approximately 20 cm, vertex at the midline of subject's body) on a low friction table top with their paretic hand. Lower root mean square error values indicate better performance. Hand path was measured with a TRACKSTAR™ three-dimensional magnetic tracker (Ascension, USA).

Pinch force was measured with an ATI Nano17™ force sensor (ATI Industrial Automation, USA). Pinch grip force is measured as the maximum voluntary force a subject can exert on a force sensor held between their paretic thumb and index finger, given two trials. Higher numbers indicate stronger pinch grip.

Table 1. Training simulations

Simulation	Training Goal	Game Play	Progression	Metric
Monkey Business 	Improve pinch grip force modulation	Subject controls monkey with pinch grip. Height that monkey jumps is in proportion to force of pinch grip. Subject makes the monkey jump to branches of varying heights.	Height of jumps are increased and time between jumps decreases as time to successful completion of the task decreases	Time/ Accuracy
Space Pong 	Finger Extension modulation	Subject plays a pong type game against the computer. Subject moves the paddle to the right by opening their fingers and to the left by closing them.	Decrease proportion of subject movement (finger extension) to paddle movement if accuracy does not improve with practice. Increase proportion when accuracy increases.	Accuracy
Space Ship 	Decreased arm elevation	Subject intercepts targets and avoids obstacles by piloting a spaceship with shoulder abduction and flexion movements	Increase target speed and obstacle density Increase workspace size as AROM increases.	Score increases with targets hit and obstacles avoided. Workspace size
Hammer 	Decreased Shoulder-Elbow Isolation	Subject hammers peg into the floor by pronating his forearm. Robot holds hammer stable over the target peg.	Decrease proportion of subject movement (pronation) to hammer movement as time to hammer pegs decreases	Peak pronation range of motion Time to hammer pegs
Piano 	Decreased Finger Individuation	Subject plays scales and simple songs. Each key is cued and the finger to press it designated.	Algorithm sets fractionation target based on performance. Utilize CyberGrasp™ to teach movement pattern if subject does not respond to algorithm.	Fractionation Time to press keys
Cups 	Decreased Shoulder-Trunk Isolation	Subject attaches virtual hand to virtual mugs and places them on virtual shelves in a 3-d workspace.	Increase volume of workspace as time to place cups on shelf decreases Recalibrate workspace weekly	Time to place nine cups on shelf Reaching trajectory length
Falling Objects 	Shoulder flexion towards midline	Subject moves a cursor to catch targets as they fall from the top of the screen. Targets drop centered on subject or in intact hemisphere.	Recalibrate workspace weekly.	Time to catch 100 targets Height of targets caught

Pinch Trace is the ability to modulate pinch grip force between zero and eighty percent of max pinch force, measured by having the subject vary pinch grip force to control a cursor tracking a sine function wave (period = 0.15 Hz, duration of 1 cycle $\approx$ 6 seconds). Lower root mean square error values indicate better performance.

TMS mapping. Subjects were tested one day before the therapy onset and one day after the end of the therapy. Subjects were seated with their arm, hand, and fingers comfortably secured in a brace to limit motion. To assure spatial TMS precision, each subject's high-resolution anatomical MRI was used to render a 3D cortical surface that is co-registered with the subject's head for frameless neuronavigation (Advanced Neuro Technology). Transcranial Magnetic Stimulation (TMS) (Magstim Rapid2, 70mm double coil) was used to determine the hotspot for the contralateral first dorsal interosseus muscle (FDI). The TMS coil was held tangential to the scalp with the handle posterior 45° off the sagittal plane. Following determination of the FDI hotspot, resting motor threshold (RMT) was calculated as the minimum intensity required to elicit MEPs > 50 μ V in the FDI muscle on 50% of 6 consecutive trials. Surface electromyographic activity (EMG, Delsys Trigno, 2 kHz) was recorded from the FDI muscles of the limb contralateral to stimulation side.

Mapping was conducted on the lesioned hemisphere of both subjects. All mapping was performed with the subject at rest and stimulation intensity set to 110% of the determined RMT (8). A 10 cm $\times$ 10 cm area surrounding the motor hotspot was marked using the neuronavigation software to provide consistent map boundaries. TMS pulses were delivered within the bounds with special attention paid to regions surrounding the hotspot territory. Real time visual feedback of the MEP time traces and neuronavigated coil position provided to the experimenter during testing maximized the map information obtained by allowing for increased density of points in excitable and border regions, with less attention given to far-away non-responsive areas (9). For each stimulation point we computed the following measures: (i) MEP as the peak-to-peak amplitude of the EMG signal 20-50 ms after the TMS pulse; and (ii) background EMG, calculated as the EMG signal in the 50 ms interval before the TMS pulse (2nd order Butterworth filter, 5-250 Hz band-pass, full-wave rectified, 20 Hz low-pass envelope). A threshold of 50 μ V was used to identify MEPs from background EMG (8). To allow comparisons across maps and sessions, MEP amplitudes and stimulation points were interpolated to a 10 cm $\times$ 10 cm mesh of 5 mm resolution centered on the M1 hotspot, using cubic surface interpolation (10, 11). Outcome measures include map area and volume, determined using double trapezoidal integration of the interpolated maps.

RESULTS

We performed feasibility testing with a single group of seven persons. Training was initiated an average of 20 (SD = 18) days post stroke. Average subject age was 63 (SD = 6.3) years (see Table 2). Please note that subject numbers correspond to the same patients for Tables 2-4 and Figure 1. One subject discontinued the protocol after being screened but prior to testing due to a second stroke, a second discontinued training after one intervention session due to fatigue. The five remaining subjects completed 8 sessions of sixty to seventy five minutes of interaction with a set of 6 simulated rehabilitation tasks in addition to completing 100% of their scheduled SIRP treatment sessions (90 minutes of PT, 90 minutes of OT and

45-90 minutes of ST per day) during the study period suggesting feasibility of this protocol. No adverse events were noted during VR training. All five subjects were able to understand the simulations well enough to participate without extensive instruction in spite of a relatively simple screening process (one three step command). Two of the seven subjects could not participate in TMS testing due to a history of seizures and three more did not consent to participating in this aspect of the study.

All five subjects made substantial improvements in UEFMA scores (Mean improvement = 6 points (SD = 2)) as well as improvements in WMFT time (average decrease = 41% (SD=35) (see Table 3). In addition, four of the 5 subjects completed at least one functional activity from the WMFT battery at post-test that they were unable to perform at pre-test. Four of the five subjects demonstrated improvements in clinical measures of proximal upper extremity function. In addition, 3 of the 5 subjects demonstrated improvements in the kinematic measure of proximal UE coordination (see Table 3). Distal UE function did not change as consistently. Only one of the five subjects demonstrated across the board improvements in all six measurements. Four of the five subjects demonstrated improvements in maximum pinch force. Four subjects demonstrated improvements in distal UEFMA (see Table 4). Figure 1 shows the changes in the distribution of the pattern of activation for the first dorsal interosseous (FDI) muscle acquired pre- and post- training for the two subjects from this sample that were medically appropriate, and who had consented to TMS testing. The MEP maps indicate an increase in both the area of activation and the volume of activation after training.

DISCUSSION

This study demonstrated the feasibility of adding one hour of intensive robotic/VR therapy to on-going rehabilitation in the acute phase of recovery post-stroke. Five of the seven subjects were able to participate in and tolerate the additional intensive activity with two of these five subjects beginning the robotic/VR therapy 5 days and 6 days post-stroke. Subjects vital sign responses to intense upper extremity activity remained stable throughout training. Subjects were supervised during 100% of the training sessions which is common for patients in the earliest phases of rehabilitation after a stroke.

This study elucidated several important issues regarding determining the efficacy of such early intensive intervention. As a group the subjects showed a 41% change in the WMFT after the two-week training period. This change is double what we have found when training patients in the chronic phase (22%). It has been demonstrated that the effect sizes reported for several clinical measures (e.g., the Frenchay, WMFT, TEMPA, ARAT, Jebsen) calculated at less than 3 months post-stroke were substantially larger than those calculated at three months or later post-stroke. The authors speculated that the observed differences in effect sizes during this time period likely reflect the inherent neuroplasticity early after stroke. However, when subjects’ outcomes were examined individually there was a noted variation in their response to treatment. Overall, there were more consistent changes in the proximal arm portions of the WMFT and the FM as well as in upper arm kinematics. Da Silva-Cameirao (3) reported a similar response on the recovery of proximal movements in a pilot study using the

Rehabilitation Gaming system in the acute phase post-stroke. This pattern of change was also noted in the kinematics of the movement. The changes in the distal clinical and kinematic measures were more varied with the exception of consistently robust changes in the maximum pinch force. The large changes in motor function, at least a portion of which will occur spontaneously, and the varied patterns of response in these subjects, would suggest that large populations will be necessary to test hypotheses effectively in this population.

An important biomarker of functional recovery is the excitability of the corticospinal system (e.g., the integrity of the motor output) (11, 12). Transcranial magnetic stimulation (TMS) induced motor evoked potentials (MEP) are an established proxy of corticospinal excitability. The initial data in this feasibility study suggest that in the days following stroke, training and recovery may be associated with an expansion of the corticospinal network (area) and strengthening of corticospinal synaptic weights (volume). This said, testing corticospinal excitability using TMS in acutely ill patients can be challenging. Less than a third of our subjects (two of seven) were medically appropriate for TMS and consented to participate. Based on our participation rate, studies planning to use TMS measures to test hypotheses in subjects with acute CVA will need to recruit from large pools of potential subjects.

In this feasibility study we have shown that providing an intensive robotic/VR intervention in the early phases post-stroke and integrating it with on-going usual care rehabilitation is a definite possibility. There are multiple challenges to this type of intervention, the inherent heterogeneity of stroke, the variation in the time course of spontaneous recovery and the confounding effect of neural restitution and compensatory functional movements. Improvements in motor performance are probably the result of several processes that occur in parallel to each other. We propose that our battery of clinical, kinematic and neurophysiological measures might be able to provide a window into the overlapping processes and help to sort out the confounding issues in the recovery of upper extremity function post-stroke.

**A COMPARISON OF UPPER LIMB MOVEMENT
PROFILES WHEN REACHING TO VIRTUAL AND REAL
TARGETS USING THE OCULUS RIFT:
IMPLICATIONS FOR VIRTUAL-REALITY ENHANCED
STROKE REHABILITATION**

ABSTRACT

Recent innovations in the field of virtual reality, such as the Oculus Rift head mounted display, provide an unparalleled level of immersion in the virtual world at a cost which is rapidly approaching mainstream availability. Utilising virtual reality has been shown to improve many facets of the rehabilitation process, including patient motivation and participation. These systems however, do not enable the user to receive feedback when interacting with virtual objects, which may influence the movement profile of a patient. Therefore, to investigate how a virtual environment influences movements during stance, participants were required to reach to a real and a virtual target. Their movements were quantified using a motion capture suit, and a virtual target was generated using the

Oculus Rift. The motions to both targets (real and virtual) were compared using a number of measures calculated to characterize the velocity profiles. Performance based indicators such as time and variance in movement were diminished when reaching to a virtual target, and movements executed in VR recruited more muscular segments than their real counterparts.

Keywords: virtual reality, oculus rift, reaching, virtual target

INTRODUCTION

Virtual reality (VR) systems have been demonstrated to be applicable to many forms of rehabilitation, improving patient motivation, and overall rehabilitation efficacy. Henderson et al. (1) found evidence that increased levels of immersion in a virtual environment provide advantages in upper limb motor skill reacquisition. They concluded that high immersion added meaningfulness to exercise movements, which increased the patient's motivation and participation in training. Rand et al. (2) demonstrated a significant increase in the usage of the affected upper extremities when using commercial video games as compared to traditional therapy. They found that providing patients with a more enjoyable and motivating experience resulted in higher frequency and intensity of movement – which is understood to be a primary contributor to the promotion of synaptogenesis, and therefore recovery (3).

The Oculus Rift is a ground-breaking VR device, capable of providing an unparalleled level of immersion in a virtual world. Combining the Oculus Rift with motion capture allows a user to see through the eyes of a virtual avatar, and interact with a virtual world using their movements. However, the display latency and lack of haptic feedback may cause disturbances in the velocity profiles when performing simple movements. Indeed, recent studies (4) have suggested that the use of head mounted displays (HMDs), such as the Oculus Rift, leads to a degree of postural instability.

Reaching to objects is a fundamental activity performed in daily life, and the ability to do so during standing is often diminished in the elderly or in persons with neurological disorders. During stance, there are significant restraints placed upon human voluntary movement, which are absent in the seated position, involving the complex coordination between movement and balance performed by the central nervous system (CNS) (5). The activation and recruitment of muscles when reaching to a real target is well understood (6), but the effect of a non-physical virtual target is unknown. In particular, it is unknown how much perceived support humans use when reaching to fixed targets to program their movement patterns. The use of VR enables a direct comparison between fixed and virtual targets in terms of the human movements produced.

Virtual reality provides an excellent opportunity to train these skills in patients, but the differences in movement patterns that are produced when moving in a virtual world are poorly understood. Research suggests that performance based indicators, such as time to complete tasks, are diminished whilst moving in VR (7), but the underlying kinematic differences causing these phenomena are unknown. This study aims to investigate the effects of VR on human movement, by comparing the underlying structure of movements (velocity profiles of the hand) during stance when reaching to real and virtual targets.

METHODS

The following subsections describe the method based on the basic procedure, the motion capture and virtual reality systems, as well as the specific data formats employed.

Procedure

Four healthy adult male participants, three healthy adult female participants, and one stroke-affected adult male participant were included in this study, each with varying degrees of experience in virtual reality.

Figure 1. Reaching to real and virtual target.

A physical target was set up at 1.3 times the length of the person's reach when feet are flat on the floor. The participants repeatedly reached for the target with their preferred hand, held that position for 5 seconds, retracted their hand to their chest, and held that position for 5 seconds (non-VR Trial).

The same task was performed while wearing the Oculus Rift (VR-Trial). A virtual target was placed in an environment, which was calibrated to be exactly at the same location as the physical target by having the participant reach for the physical target, then setting the location of the virtual target to the in-game location of the hand. The physical target was then

removed. The only cue given concerning performance was the colour of the virtual target, which changed from green to red upon contact with the virtual avatar's hand (see Figure 1).

Motion-capture/VR system setup

Participants' movements were recorded using an XSENS MVN BIOMECH inertial motion capture suit. The suit was calibrated at the beginning of each session, to ensure that the readings for the real and the virtual tests were captured using the same calibration values. Recordings were captured by the associated software MVN Studio PRO, which provides the velocity data in x , y and z directions for 23 body segments at a capture rate of 120 Hz.

The motion capture data was streamed in real-time into the Unity game engine as a number of quaternion rotations, representing each segment of a 23 point kinematic map. This was then used to cause an avatar to reproduce the same movement.

The Oculus Rift HMD became the virtual eyes of the user. This HMD provided rotational information, which controls the orientation of the avatar's head in Unity, so that the user was able to freely look around the virtual world. Looking down, the user could see his/her virtual avatar's body, which was moving to match the person's own movements.

Quantifying the data

The motion data for each reach movement was exported from MVN Studio. Only the initial component of the reach movement to the target (fixed or virtual) was included, the motion data for return of the finger to the initial starting point being discarded. The beginning of the motion was specified as the point where the velocity magnitude of the hand reached 5% of the maximum achieved velocity.

Figure 2. Velocity profiles of characteristic results, X marks where the target was reached.

All data sets exhibited a similar basic shape: a period of acceleration (activation) to maximum velocity, then deceleration (settling) towards the target (see Figure 2).

A number of variables were extracted from the data (see Table 1):

- 1) VMax – the maximum movement velocity.
- 2) ActGrad – the gradient for the acceleration phase: how quickly the maximum velocity was achieved.
- 3) Time to Target – the time used to reach the target.
- 4) Symmetry Ratio – the ratio between the acceleration and deceleration phases.
- 5) Settle MSE – the amount of variation in the settling segment.
- 6) Holding MSE – the amount of variation while holding position at the target.

Table 1. Non-VR vs. VR results for stroke-affected participant and average of healthy participants

	V _{Max}	ActGrad	Time To Target	Settle MSE	Holding MSE	Symmetry Ratio
Avg. Non-VR trial	0.94	0.08	1.48s	0.01	0.0007	0.68
Avg. VR trial	0.81	0.02	2.46s	0.04	0.003	0.29
Non-VR trial (stroke)	1.18	0.03	1.76s	0.06	0.001	0.26
VR trial (stroke)	0.99	0.02	2.97s	0.06	0.003	0.15

The velocity profiles recorded showed significant differences in shape between the VR and non-VR trials. The time to reach the target in VR trials took, on average, 0.64 seconds longer than non-VR trials for the healthy participants, and 1.21 seconds longer for the stroke-affected participant. The VR trials showed significant oscillation during the settling period (VMax to target contact) for the healthy participants, while the stroke affected participant showed a much higher level of oscillation, independent of whether it was a VR or a non-VR trial.

Figure 3. Pelvis velocity profile of 7 reaches in VR and Non-VR trial (Non-VR magnified 10x).

The MSE was calculated against a reconstruction of a stereotypical movement profile, created using the assumption that an ideal motion would accelerate and decelerate smoothly towards the target. The MSE calculated for all phases of the movement was significantly higher for the VR trials.

DISCUSSION

The results show that the movement profile of reaching to a virtual profile resembled that of reaching to a real target; however the deceleration phase took significantly longer, resulting in a longer time to complete the movement. The level of experience with VR did not seem to have a noticeable effect on the results, however this was the first time any of the participants had used motion capture in combination with an HMD. Participants did, however, seem to slightly improve their VR symmetry ratio over the trial, indicating that the subjects could possibly be trained through repetition so that their movements in VR more accurately resemble those in reality. This suggests that VR could potentially be used to enhance traditional movement retraining.

Upon inspection of the velocity profiles of other body segments, it was found that in general the VR movements recruited other segments significantly more than the non-VR movements. Figure 3 shows the velocity profile of the pelvis of one of the participants over 7 reaches. The non-VR movement registered almost no activation of the pelvis, while the VR movement shows significant pelvis activation. This result suggests that the muscular activation strategies employed in movements in VR are different to their real counterparts, and future research will be required to determine exactly how these activation strategies differ.

The fourfold increase in settling MSE indicated that subjects experienced uncertainty in the position of both their hand and the target, which validates previous research in virtual target acquisition (7). The lack of physical target to rest against for the 5 second hold accounted for the increased hold MSE.

CONCLUSION

Differences between the VR and non-VR trials were observed. In particular, reaching during standing to a VR target required a greater degree of control of the arm during the deceleration phase than reaching to a fixed target. These results must be considered in any further research into VR-enhanced rehabilitation, particularly when utilising HMDs such as the Oculus Rift, because moving in a virtual world does not produce the same movement patterns as moving in the real world. In general, actions in VR took longer to accomplish than their real counterparts, and displayed a higher level of variance in motion, indicative of a degree of uncertainty and instability. VR movements appeared to recruit more body segments in the movement than non-VR. Further study is required to determine if these phenomena are limited to subjects inexperienced with VR, which would mean that subjects could be trained and their movements improved through repetition. Whether this effect has an impact on the efficacy of motor rehabilitation remains to be seen.

ABSTRACT

Tracking technologies allow users to interact with virtual reality environments. Most research regarding tracking systems has focused on studying their performance parameters. However, even though subjective parameters also determine the responses evoked by the virtual reality experience, little effort has been made to study their influence. The objective of this paper is to determine the subjective perceptions of healthy subjects, individuals post-stroke, and physical therapists after using three tracking technologies (optical, electromagnetic, and skeleton tracking) to interact with a virtual rehabilitation exercise. Three groups participated in the experiment, involving healthy subjects (n = 19), individuals with stroke (n = 22), and physical therapists (n = 14). Participants belonging to the healthy and stroke groups interacted with a stepping exercise in three 15-minute trials using the three tracking systems. After each trial,

participants filled in an ad-hoc questionnaire to report their subjective experiences. Physical therapists monitored 45 training sessions with the virtual rehabilitation exercise, 15 sessions with each tracking technology in randomized order. After the last session, they evaluated the three tracking systems completing another questionnaire. By and large, results showed that healthy subjects and physical therapists mainly preferred the skeleton tracking solution rather than the optical and electromagnetic solution (in that order). However, individuals post-stroke preferred the optical solution to the other options. In conclusion, subjective perceptions and preferences are far from being constant among different populations, thus suggesting that these considerations, together with the performance parameters, should be taken into account when designing rehabilitation systems.

Keywords: motion tracking systems, virtual rehabilitation, virtual reality, stroke

INTRODUCTION

Virtual reality (VR) can recreate synthetic environments that can be tailored to provide specific sensory stimulation in different channels. However to immerse individuals in an alternative reality, not only the stimulation is required, but also the virtual environment (VE) must react in a similar way to the real world, at least in certain aspects (1). Interaction with the VEs has been a technical challenge through the years. In order to detect and transfer the users' movements to the VE, different tracking solutions have been proposed. Tracking systems estimate the location and orientation of known targets with six degrees of freedom and transfer the data to the virtual world in real time (2). Traditionally, three main physical principles have been used to locate the targets, therefore classifying the tracking systems as either optical, electromagnetic, or inertial (or hybrid solutions combining the mentioned mechanisms).

Recent advances in technology have given rise to cheaper motion tracking solutions based on depth sensors, such as the Microsoft® Kinect™ (Microsoft®, Washington) or the ASUS® Xtion Pro (ASUS®, Taipei), both equipped with the PS1080 chipset (PrimeSense™ Ltd, Tel Aviv). According to the previous classification, these solutions can be considered as optical-based, because they estimate the depth information of a scene, but they are complemented with a statistical method to estimate the main joints of the human silhouettes present on the captured scene (3). Even though the classical definition of tracking systems requires the location of a target with six degrees of freedom, the location of the joints provided by the skeleton tracking is enough to interact with a great number of VE. The low cost of these devices, their comfort (no wearable sensors are needed), and their off-the-self availability have facilitated their widespread use (4, 5).

All the tracking technologies present different characteristics that are inherent to the physical principle on which they are based. Consequently, a tracking system can be defined by some parameters, such as accuracy, jitter, drift, and latency (2). Several studies have compared the performance of different tracking solutions according to these parameters (6-8). However, even though subjective considerations also determine the VR experience, thus modulating the immersion and presence of the users (9), limited research has focused on these aspects when using tracking systems. Interestingly, people with neurological impairments, as with individuals post-stroke, who are one of the target groups for VR-based rehabilitation

systems, may present sensory, motor, cognitive, and emotional impairments that can affect their interaction with the world (10, 11), and consequently, their subjective perceptions when using a tracking system.

The objective of this study was to evaluate the subjective perceptions elicited when using three different tracking technologies (optical, electromagnetic, and skeleton tracking) in three different populations: healthy subjects, individuals post-stroke, and physical therapists.

METHODS

Three different groups of participants were recruited. The age of healthy subjects and individuals post-stroke was matched.

The inclusion criteria in the healthy group were: (i) age ≥ 55 and < 80 ; and (ii) absence of previously reported motor or cognitive limitations. Individuals with previous experience with VR-based systems were excluded.

The inclusion criteria in the stroke group were: (i) age ≥ 55 years old and < 80 years old; (ii) chronicity > 6 months; (iii) absence of severe cognitive impairment as defined by Mini-Mental State Examination (12) cut-off > 23 ; (iv) able to follow instructions; (v) ability to maintain stride-standing position for 30 s without holding onto or assistance from another person as specified in the Brunel Balance Assessment, section 3, level 7 (13); and (vi) a Berg Balance Scale (14) score ≥ 41 . The exclusion criteria were: (i) individuals with previous experience with VR systems; (ii) individuals with severe dementia or aphasia; (iii) individuals whose visual or hearing impairment did not allow the possibility of interaction with the system; (iv) individuals with hemispatial neglect; and (v) individuals with ataxia or any other cerebellar symptom.

The inclusion criteria in the physical therapists group were: (i) physical therapy degree; and (ii) ≥ 2 years of experience in neurorehabilitation. Therapists with previous experience with VR systems were excluded.

Brief description of the tracking systems

Three different tracking solutions were used in this study: optical, electromagnetic, and skeleton tracking. The optical tracking consisted of two infrared cameras – the OptiTrack™ V100:R2 (NaturalPoint®, Corvallis) – aligned in the same plane (see Figure 1a). This setting allowed the location of spherical reflective markers present in the intersectional field of view of both cameras using epipolar geometry (15).

A G4™ (Polhemus™, Colchester) tracker was used as the electromagnetic solution (Figure 1b). Essentially, the tracking consists of an electromagnetic source and different sensors that are connected to a hub, which supplies them with power and transmits the tracking data to a PC. The sensors detect the electromagnetic field generated by the source and estimate their location and orientation (16).

With regards to the skeleton tracking, a Kinect™ and the Kinect for Windows SDK were used to track the body joints (see Figure 1c). This tracking solution estimates the depth

information of the scene, detects the human silhouettes present in the depth images, and applies a statistical method to fit a skeleton in the silhouettes (3).

A summary of the performance parameters of the tracking systems, principally defined by the manufacturer, is depicted in Table 1.

Figure 1. Tracking systems under study.

Virtual environment

A VR-based stepping exercise was used to assess the experiences of the participants of the three groups when using different tracking technologies (17). The VE consisted of an empty scenario with a checkered floor whose center was indicated with a darkened circle. The participants were represented by two feet that mimicked the movements of their own feet in the real world with a third person perspective (see Figure 2a). Initially, both feet appeared in the center of the circle. Different items rose from the ground in the surroundings of the circle, and disappeared after a few seconds. The objective of the exercise was to step on the rising items with the nearer foot while maintaining the other foot (the support foot) within the boundaries of the circle. After stepping on the items, the leg had to be drawn towards the body and placed within the circle to trigger the next target item.

The ankle joints (tibiotalar) of the participants were located and transferred to the VE by the tracking systems. In the optical and electromagnetic solutions, the joints were identified with reflective markers or electromagnetic sensors, respectively, fixed with a Velcro strip. The hardware setting of the VR system consisted of a standard PC, a 42" LCD screen, and one of the tracking systems described in the previous section (see Figure 2b and 2c).

Virtual reality based stepping exercise: a) snapshot of the virtual environment; b) participant interacting using the optical solution; c) participant interacting using the skeleton tracking solution.

Figure 2. Virtual reality-based stepping exercise.

Procedure

Three different VR units were installed in the physical therapy area of a neurorehabilitation center, each equipped with a different tracking system. The experiences of all the participants after using the three systems were collected through two ad-hoc questionnaires (A and B). Questionnaire A collected the experiences of healthy subjects and individuals post-stroke. Questionnaire B collected the experiences of physical therapists. The first four questions of both questionnaires evaluated the same topics.

Participants belonging to the healthy and stroke group interacted with the stepping exercise in three 15-minute trials using the three tracking systems in counterbalanced order. The level of difficulty was determined by a physical therapist, who supervised all the sessions, to define an attainable but challenging task. After each trial, participants filled in questionnaire A. Questionnaire A consisted of six items to be assessed: (i) fixation speed of the sensors/markers; (ii) ease of the calibration; (iii) accuracy of the represented movements; (iv) robustness; (v) comfort; and (vi) order of preference. Responses to the first five items were rated on a 5-point Likert scale, where 1 means “very little/not at all” and 5 means “very much”. Responses to the last item were estimated as a percentage of preference.

The VR-based system was integrated in the physical therapy program. Patients who were attending a motor rehabilitation protocol in the neurorehabilitation center were assigned to train with the system according to their motor condition and expected benefits. Physical therapists monitored 45 training sessions with the VR-based exercise, 15 sessions with each tracking technology in randomized order. After the 45 sessions, the therapists, who were uninformed of the costs of the tracking systems during the entire study, were finally informed and filled in the questionnaire B for the optical, electromagnetic, and skeleton tracking. This questionnaire consisted of eleven items that assessed: (i) fixation speed of the sensors/markers; (ii) ease of the calibration; (iii) accuracy; (iv) robustness; (v) ease of fixation; (vi) insensibility to changes in the clinical setting; (vii) ease of assistance; (viii) maintenance; (ix) working range; (x) value for money; and (xi) order of preference. As in questionnaire A, the first tenth items were rated on a 5-point Likert scale and responses to the last item were estimated as a percentage of preference.

Statistical analysis

Demographical comparisons among groups were performed with independent sample t-tests and Chi-squared or Fisher exact tests, as appropriate. Repeated measures analyses were performed using the non-parametric Friedman test (χ^2 , p values) to determine within-group differences between tracking systems (NaturalPoint® OptiTrack™, Polhemus™ G4™, and Microsoft® Kinect™). When the Friedman test yielded a significant effect ($p < 0.05$), post hoc analysis was performed using a Wilcoxon signed-rank test for pairwise comparisons between tracking systems. The α level was set at 0.05 for all analyses. All analyses were computed with SPSS for Mac, version 20 (SPSS Inc., Chicago, USA).

RESULTS

After inclusion/exclusion criteria, the healthy group consisted of 19 individuals (12 males and 7 females, 60.8 ± 4.1 years old) and the stroke group consisted of 22 individuals (15 males and 7 females, 60.1 ± 7.0 years old). The stroke group included ischemic ($n = 11$) and haemorrhagic stroke ($n = 11$), and presented a chronicity of 272.4 ± 56.7 days. Of all the physical therapists working in the neurorehabilitation center, 14 therapists (6 males and 8 females, 31.8 ± 2.4 years old) satisfied the criteria and accepted to be included in the study.

Results of the three groups to the questionnaires showed that healthy subjects and physical therapists mainly preferred the skeleton tracking solution rather than the optical and electromagnetic solution (in that order). However, individuals post-stroke preferred the optical solution over the other options (Table 2).

DISCUSSION

Scores to the different items of the questionnaire are discussed below.

Fixation speed of sensors/markers. All the groups reported the Kinect™ as the least time consuming system, followed by the optical and the electromagnetic solution. Despite the significant difference between the skeleton and the optical tracking reported by the healthy and professional group (a difference in mean values of 0.8 and 1.4, respectively, respectively), individuals with stroke did not find this difference as relevant (0.1 difference in mean value). The fixation speed of the electromagnetic sensors was reported to be the lowest by the three groups. Interestingly, the professionals evaluated it with the lowest score, which can be explained by the fact that they also had to be careful with the position of the wires to avoid tangles.

Ease of calibration. No significant differences among tracking systems were reported by the healthy group. However, the stroke and professional group found the calibration for the skeleton tracking to be significantly more difficult than for the other systems ($p < 0.001$), since it required the participants to move to be tracked. This fact made the task more difficult for individuals with stroke, who presented motor impairments, as reported by clinicians and themselves.

Accuracy. The optical tracking system was reported to be the most accurate solution by all the groups ($p < 0.05$), consistent with the results of the performance study. The same

ranking order was found in the responses from healthy individuals and physical therapists. Individuals with stroke, however, reported the Kinect™ to provide the lowest accuracy ($p < 0.05$). The presence of motor impairments could have led individuals with stroke to execute irregular movement patterns and postures that could affect the body parts recognition and skeleton fitting processes.

Robustness. Similar conclusions can be inferred from the results of the robustness. All the groups defined the electromagnetic tracking solution as the most robust solution ($p < 0.05$), followed by the optical and the skeleton tracking system. Errors in the pose estimation could cause momentary maladjustments between the real and the virtual pose, which could be interpreted as a lack of robustness, especially by individuals with stroke and physical therapists, who reported the lowest scores (3.4 ± 0.7 and 3.3 ± 0.8 , respectively).

Comfort. The skeleton tracking system, which did not require sensors, was evaluated as the most comfortable solution by healthy subjects and individuals post-stroke ($p < 0.001$), followed by the optical and the electromagnetic solution. Differences between the optical and the electromagnetic tracking systems were also reported by the healthy ($p < 0.05$) and stroke ($p < 0.001$) groups. While the optical solution only required participants to wear reflective markers attached to their ankles, the electromagnetic solution also required them to wear a hub held to the waist of their pants, which was connected through wires to the sensors.

Ease of fixation. The professional group evaluated the skeleton tracking with the highest score, followed by the optical and the electromagnetic system (consistent with the scores in the fixation speed), which required therapists to fix the markers on the ankle joint of the patients. The electromagnetic solution, in addition, required the fixation of the hub and the careful placement of the wires in order to avoid tangles. The time and ease of fixation are crucial factors that must be minimized in clinical applications, where time is limited and should be dedicated to the physical therapy (18, 19).

Insensibility to changes in the clinical setting. The therapists considered that the skeleton tracking system was the least susceptible system ($p < 0.001$). However, the overall scores were low in comparison with other items. The optical solution was sometimes affected by reflections caused by chairs, room dividers, plinths, etc., elements commonly present in the clinical setting, or even by the sunlight. Even though these issues can be avoided by removing these elements from the field of view of the cameras or by closing the blinds, physical therapy units are dynamic areas where the spatial distribution is constantly changing and sunlight is appreciated. The electromagnetic tracking system proved to be the most susceptible solution to environmental changes.

Ease of assistance. The therapists reported that the electromagnetic tracking system was the solution that better allowed them to assist the patients. The physical principle of the G4™ made the performance of the system possible even when the therapists were between the source and the sensors. It allowed them to freely assist the patients from any position, and even to manipulate their extremities if needed. The optical tracking, on the contrary, required that the cameras had direct line-of-sight to the markers. The assistance, although possible, had to be provided from behind. Similarly, the Kinect™ required direct line-of-sight with the participants' complete silhouettes. Since the statistical method to detect the body segments was trained with isolated human poses, when therapists were close to the patients, manipulating or touching them, the system was not able to fit a skeleton to the resulting silhouette. Therapists had to hide from the view of the Kinect™ in order not to affect the tracking, which resulted in significant lower scores (2.5 ± 0.9 , $p < 0.001$).

Maintenance. With regards to maintenance, the therapists found that the need for recharging the hub of the electromagnetic tracking system after some hours of use was a limiting factor ($p < 0.001$). The other tracking solutions did not required special maintenance.

Working range. The professional group reported that the skeleton tracking system provided the largest working area, followed by the optical tracking system and the electromagnetic solution, which had significant lower scores ($p < 0.05$), consistent with the experimental results.

Value for money. The mass-produced Kinect™, which had the lowest price, achieved the highest score ($p < 0.001$). Scores to the other tracking solutions were also consistent with their price.

Preference. The healthy group mostly preferred the Microsoft® Kinect™ (79.0%), to the other tracking systems, which is consistent with their scores on the comfort item. Remarkably, this group did not experience significant problems when interacting with the system, as the Kinect™ is oriented towards healthy population. On the contrary, the stroke group mostly preferred the optical tracking system (68.2%). The issues mentioned derived from an incorrect skeleton fitting, which was more common in this group due to their motor restrictions, and which could have influenced their choice. These facts should be especially taken into account when working with individuals post-stroke, since they are likely to present behavioural problems (20), such as irritability or depression, which can make this population particularly prone to frustration and reduce the benefits of rehabilitation (21). In consequence, the use of the Kinect™ could be restricted to subjects with specific motor conditions. The therapists mostly preferred the skeleton tracking (57.1%), slightly over the optical solution (35.7%). This result could be explained as a trade-off between both systems. In spite the ease and speed of the Kinect™ startup and its ease of maintenance, the aforementioned issues with the Kinect™ can make the interaction of some patients difficult. The optical solution can overcome most of the interaction problems but it presents, however, some environmental restrictions (mainly light-related effects) that can affect its clinical use. An ideal situation allowing the use of these two tracking options, and the required space in the physical therapy unit, could satisfy all these requirements.

To summarize, our results show that subjective perceptions and preferences are far from being constant among different populations, thus suggesting that these considerations, together with the performance parameters, should be also taken into account when designing a rehabilitation system. In general, the skeleton tracking system was preferred by therapists and healthy individuals, and by a great number of individuals post-stroke. With regards to the therapists, though the assistance with skeleton tracking system initially posed a challenge for them (reported as the main issue of the technology), once they knew its functional limitations, they were able to provide assistance to the patients. This fact, together with its affordable cost, could have led them to finally adopt the skeleton tracking solution over the other systems, and can be the reason why they are using it currently in their daily practice.

ABSTRACT

Motion controlled video games have been shown to have a positive effect for physical rehabilitation on the upper extremity in stroke survivors when combined with conventional physical therapy. The study investigates the therapeutic potential of the Microsoft Kinect for the Xbox360, a multimodal gaming peripheral. The Kinect allows users to interact with games using bodily motions and gestures. A list of important joint motions and movement synergies were identified by looking at leading stroke motor function tests for the upper limb. These have been verified by working with Occupational Therapists. A study group of occupational and physiotherapists were asked to record their experience of playing three Kinect mini-games and evaluate them with respect to their motor function requirements and exertion for each identified joint motion. Quality information was also gathered relating to the perceived usability and safety issues that could arise by presenting the device to a stroke survivor. The Kinect provides opportunities for gross arm movement exercise, while the requirement for highly raised

arm movements will present a potential barrier for stroke users. Fine motor control movements of the hand and fingers are not tracked sufficiently for effective rehabilitation of the hand. A probable risk of falling while using the Kinect, and potential injury from overexerting the impaired limb while playing existing games, were also identified. We conclude that as the experience have been designed for able bodied users, the games present significant barriers for using the Kinect as a commercial off-the-shelf system for stroke rehabilitation.

Keywords: kinect, rehabilitation, upper extremity stroke, games, commercial off-the-shelf

INTRODUCTION

Stroke is the third most common disease in the UK with over 100,000 cases annually (1). Stroke is also the leading cause for long term disability (2). The cost of treatment and dealing with the long term disabilities afterwards is estimated to cost the UK economy £8.9 billion per year (3). Impaired arm function is a common effect of a stroke seen in around 70% of stroke cases; 40% of patients will have a completely non-functioning arm (4). Rehabilitation of the impaired limb is key to helping the stroke survivor regain independence. By allowing more stroke survivors to live independently the costs of providing disabled services and care can be reduced.

Physical rehabilitation is concerned with helping stroke survivors to regain control and coordination of the impaired upper limb. This involves direct contact with physical and occupational therapists to help the survivor develop and perform a set of exercises designed to help regain control in the upper extremity. Physical rehabilitation in this way can be limited by the therapist's availability; giving survivors more opportunity for rehabilitation increases the expected recovery (4). Following discharge from hospital the survivor may be required to travel to outpatient facilities for rehabilitation; this can be problematic for survivors with poor mobility (common following stroke) or who live in remote areas. The sudden and often unexpected stroke will have a significant effect on the survivor's life, making tasks that were once easy extremely difficult. It is therefore unsurprising that depression is common amongst stroke survivors. It is important that the survivor remains motivated and engaged with their rehabilitation especially in the early stages when the expected recovery amount is at its maximum (5).

Motion controlled video games have been shown to have a positive effect on physical rehabilitation of the upper extremity in stroke survivors when combined with conventional physical therapy (6-8). These games consist of an input method that requires movement of the upper extremity causing the player to exercise the impaired limb whilst playing the game. The game itself provides a motivational context that is fun and engaging for the player to interact with (9). While much research in this area has worked with bespoke systems and games, some research has been done into using commercial off-the-shelf gaming systems (COTS) for use in upper extremity stroke rehabilitation. As COTS systems are designed to be used in the home they offer the possibility of providing survivors with low cost systems that they can use to carry out rehabilitation at home (10). This could allow survivors to exercise at a level they are comfortable with, independent of physical or occupational therapists. It also offers a valuable opportunity to survivors who are unable to frequently travel to outpatient centres to

engage with rehabilitation activity. Low cost independent rehabilitation solutions may provide a cost effective way for long term rehabilitation which is currently limited by therapist resources (11, 12).

Historically the literature relating to COTS gaming systems for use in stroke rehabilitation has focused on two systems, the Playstation EyeToy and the Nintendo Wii. More recently however, following the launch of the Kinect system in late 2010, there has been a surge of interest in the investigation of the Microsoft Kinect and the role it can offer in this context.

The PlayStation EyeToy is a small camera that attaches to the PlayStation 2 gaming system. Functionally it is equivalent to a low cost USB web camera. The device outputs a low resolution colour image. The system then looks for any differences in colour at each pixel over time (between captured frames) to detect any motion at that pixel's location. As the system only looks for motion it is unable to distinguish between the player's movement and any background object. The system does not implement any pose tracking, so is unaware of the player's actual pose or position. To account for this the player is usually asked to stand or sit in a fixed position and use their arms to create the necessary motions. Rand et al. (13) tracked the scores and enjoyment of a group of stroke survivors and a group of healthy elderly users while playing several EyeToy games. Comparing the results showed that both groups found the experience enjoyable and highly motivating. However, the stroke group had significantly lower game scores; this can be accounted for by the stroke group reporting fatigue in the impaired limb, preventing them from playing as effectively. It is mentioned that the option to control the speed and difficulty of the games is not present but in this context would be desirable. Yavuzer et al. (14) reported a controlled, assessor blinded trial over four weeks where one group of stroke survivors took part in treatment using the EyeToy. The control group spent the same amount of time observing the game but not partaking. At the end of the four week trial the EyeToy group scored significantly higher when measured with the functional independence measure (FIM).

The Nintendo Wii uses a handheld controller device that can detect its position relative to a sensor bar mounted on the display device and the acceleration force on the controller. Like the EyeToy, the Wii is not able to perform body pose estimation as it can only gather positional information of the controller device. For most games this is assumed to be in the user's hand so can therefore be used to determine hand position. Joo et al. (15) found a slight increase in Fugl-Mayer assessment scores following two weeks of physical therapy using the Nintendo Wii. All subjects found the games enjoyable or very enjoyable. Problems were encountered during the study as some subjects had trouble holding the Wii controller due to poor hand motor control, therefore a custom strap was used to allow the user to 'wear' the controller rather than hold it. Saposnik et al. (16) compares using the Wii to conventional recreational therapy, finding that the Wii offers significant improvement in motor functions measured with the Wolf motor function test; Mouawad et al. (17) also found similar positive results.

The Microsoft Kinect for the Xbox360 is a multimodal gaming peripheral. Its primary input method is a novel low cost ranging (depth) camera that is used to drive a full body skeletal pose estimation system. This allows users to interact with games using bodily motions and gestures. Unlike other current motion controlled gaming systems the Kinect is marker-less so does not require the user to hold or wear any peripherals. The ranging camera allows position estimation in three dimensions allowing complex body poses to be tracked.

The accuracy and consistency of the Kinect sensor has been evaluated both in terms of its ability to measure the position of objects (18, 19) and upper body joint rotations (20). These studies suggest that it performs very well. It is however important to acknowledge that under certain circumstances use of the peripheral can be problematic. Some of these limitations are inherently a property of the technology itself. The use of projected infra-red light precludes the use of the sensor in areas of bright natural sunlight and, being camera based, occlusion is a big issue, particularly where the hand or arm pose is unconventional due to a disability.

Lange et al. (21) utilised the Kinect in a trial for balance training of adults with neurological injury. This study highlighted the difficulty of achieving the “calibration pose” necessary for the skeletal tracking to initialise properly. Of the twenty participants in this study, eight were unable to achieve this pose and the remaining twelve required the assistance of a clinician to manipulate the upper limb into a position suitable for calibration. Pastor et al. (22) also noted the problems with supporting the weight of an impaired upper limb, utilising the Kinect in a downward pointing manner so that a table top could provide support. These studies were based upon bespoke software solutions. The current crop of COTS games have the added drawback of also requiring the player to stand while playing, further exacerbating the potential usability issues associated with using the system and raising further questions about whether it has any potential as a COTS device for home rehabilitation. However the study conducted by Chang et al. (23) concluded very favourably in terms of the utility of the device, noting a significant improvement in motor function as well as recording high levels of motivation and recommending further investigation.

In this paper we present our findings from a study to evaluate the Kinect for safety and suitability as a COTS gaming system for stroke rehabilitation. The study also sought to identify areas that a bespoke system based upon Kinect hardware could improve upon, thereby enhancing, the rehabilitation possibilities beyond those available within existing commercial titles. The study’s focus was on identifying exercises of interest to upper extremity rehabilitation that are encouraged and facilitated by the system. Full upper extremity rehabilitation requires multiple exercises across a number of joints in the upper extremity. It is important to identify which regions the Kinect is effective at exercising so that its potential as a tool for rehabilitation can be assessed, as well as evaluating the usability of the Kinect device within the physical limitations of a stroke user group. The Kinect system is a full body skeletal tracking system. Games designed for the Kinect are built with able bodied users in mind, therefore as noted by Lange et al. (21) only a subset of available games, or game elements may be usable by a stroke user group with limited physical capabilities.

Safety concerns surrounding usage of the Kinect with a stroke user group were also explored. Stroke survivors with upper extremity deficits commonly have accompanying lower extremity problems, affecting balance and mobility. This can put the stroke survivor at a greater risk of falling. Therapists were asked to assess the presented games to identify if they would put a stroke user at a risk of falling. They were also asked to assess if the Kinect encourages exercises that could have a negative effect on the stroke survivor’s recovery.

As Xbox Kinect has over 140 games from first and third party developers only a small number of these could be included into the study due to limited resources and practicality of the study duration. Potential games were examined against the following criteria:

- Short experiences that a user is able to learn and play quickly are desirable considering the time constraints of the study.

- A complete round of a game should take no more than a few minutes to complete.
- The game must provide adequate instructions for a non-gamer to easily understand and play.
- The game must remain playable for a user with a low level of physical ability.

Figure 1. Kinect Sports for the xbox360 ©Microsoft 2010.

Using these constraints the game ‘Kinect Sports’ was selected. It is perhaps interesting to note that “sports” was a theme requested by participants in the Lange et al. study (21). Kinect Sports (see Figure 1) is a series of mini games based on real world sporting activities. As such the rules of the games are easy to learn even to non-gamers as they match the real world counterparts. The mini game format allows short game experiences to be played quickly and repeatedly without spending a significant amount of time operating menu systems. From a selection of six mini games, two were selected: Bowling and Table Tennis. These were chosen in order to compare a game that requires the user to react in a limited time (Table Tennis) with one where the user is given time to cognitively process and plan the activity (Bowling).

METHODS

The study was conducted over several repeated sessions with different occupational therapists. Therapists were allowed to participate individually or in pairs. When in pairs, each participant was required to play at least one round of each game individually, while the other

observed. Individual participants would watch a demonstration round provided by the session conductor. This was designed to allow participating therapists to observe the system from a first and third hand perspective.

At the beginning of each session the occupational therapists were given a brief demonstration of the Kinect system by an experienced user leading the session. The session conductor demonstrated how to start the Kinect system, navigate to the first game to play, start the game and give a brief demonstration of how to play the game. The system was then restarted and each occupational therapist in turn was asked to perform the start-up steps and play the game for several minutes including at least one full round of the game. After each occupational therapist had a chance to use the system and experience the game they were presented with a questionnaire to gather feedback from their experience. Participants were allowed to continue playing the game during the questionnaire. This process was repeated for each of the two mini games.

Population

The purpose of this study is to primarily evaluate if the Kinect is safe for use with a stroke group. Therefore no stroke survivors were involved at any stage of this study. The study population consisted of qualified occupational and physical therapists with experience of working with a stroke population. Six participants were recruited for the study. All six participants completed the study.

Data collection

Data was collected by questionnaires completed by the participants. The questionnaire asked participants to rate the minimum joints functionality required at each joint needed to meaningfully participate in the game, how exerting the exercise on each joint was during play and how much they felt the game encouraged them to use individual joint movements.

Participants were also invited to discuss their experience of playing each game. They were asked to focus on any potential safety issues they could foresee when presenting the Kinect system to a stroke population.

RESULTS

To visualise the results they have been graphed to show the mean score, standard deviation and range of the answers given. Of the two games tested, bowling was found to be more suitable for a stroke survivor as it required less arm and shoulder functionality to play. As shown in Figure 2, bowling required a moderate to high level of shoulder mobility to play, a moderate amount of elbow movement and very little wrist and hand movement. Comparatively table tennis, as shown in Figure 3, is far more intensive and requires a much higher level of motor functioning. This could be due in part to the time limitations of each activity. Bowling allows the player to take an indefinite amount of time to bowl each ball. Table tennis by contrast requires the player to make timed reactions to the computer

opponent. Cross body movements were required to perform backhand shots, this probably explains the increase in the amount of high intensity shoulder movements required.

Both games required little to no hand and wrist movement. This fits with our understanding of how the skeletal tracking algorithm works as it is unable to track wrist rotations and hand pose. Therefore we would expect games not to require wrist and hand movement as they are unable to detect them. Therapists did however feel that the games encouraged a greater range of joint movements than the system required. As shown in figure 4, therapists found themselves using hand and wrist motions when playing. As the games mimic real world activities the players may feel the need to match the normal movements even if they are not required by the Kinect games. In bowling, therapists found themselves making hand grip and release movements when picking up and throwing the ball.

By encouraging joint movements in this way the games could provide a wider rehabilitation benefit to more joints in the arm than are traceable by the Kinect camera. However as the joints are not tracked there is no guarantee that the user is performing them. This may be useful in a supervised therapy session where the therapist can observe the patient's movements. However in an independent usage situation there would be no record of the patient's hand movements and would therefore be of reduced usefulness for telerehabilitation.

Therapists were also asked to rate how intensively they were using each joint during play, as shown in Figure 5. Most joint movements were found to be low to medium intensity. This is good as many stroke survivors will have a weakened upper limb and may fatigue quickly when performing intensive tasks. Shoulder flexion and extension movements were found to be very intensive. This is because the game requires the user to make a large swinging movement at the shoulder. This is problematic for a stroke survivor as many will not have the required range of motion. This could present a barrier that they are unable to overcome and thus not be able to use the game.

Qualitative findings

Therapists were asked to provide additional feedback about their experience. Common feedback included raising concerns about the balance risks while using the device. As the game does not work in a seated position, players must be standing. Many stroke survivors have reduced mobility, placing them at an increased risk of falling. Because of the motor impairments stroke falls can be extremely dangerous as often the victim is unable to break the fall using their upper limb. This makes the Kinect a potentially dangerous system to use for rehabilitation, especially when unsupervised. Several therapists also expressed the desire for seated play as many survivors are unable to stand unaided so could not use the system. When developing bespoke games, allowing them to be played in a seated position should be considered a high priority.

Concerns over the game's graphical interface were also raised. Kinect Sports is designed to mimic sporting television coverage. This includes fast camera cuts and pans; detailed environments including crowds and decorative lighting; and statistical overlays that appear periodically. Cognitive deficit can accompany motor deficit during stroke, and many stroke survivors will not be familiar with video games. Efforts should be made to provide a clearer graphical interface.

DISCUSSION

The off-the-shelf Kinect game Kinect Sports was evaluated to assess the feasibility of using it in its current form as a stroke rehabilitation aid. Two games from the title Kinect Sports were evaluated – bowling and table tennis. It was found that both titles were highly exertive on the shoulders and arms, while no wrist, hand or digit functionality was required at all. Although it was felt that wrist and hand movements were encouraged through the context of the exercises, as the Kinect does not track these motions it cannot be guaranteed that the user is performing them during play. Due to the high level of arm functionality required, it is likely that the games would only be useable by stroke survivors who have recovered a significant amount of motor functionality. Qualitative information was also gathered from therapists during the study, who believed the exercises combined with the requirement to stand while playing presented a real danger of fall and injury during play. It is concluded that off-the-shelf Kinect games are not suitable for most stroke survivors for unsupervised rehabilitation.

Adaptations that could be made to the evaluated games would be to allow play from a sitting position to reduce the risk of a fall and further injury. The Kinect Sports game does not support seated play but a small number of Kinect COTS games do allow this, e.g., Fruit Ninja Kinect and Kinectimals. Our results also showed that games require a high degree of joint functionality to play especially with regards to shoulder movements. This limits the potential audience to stroke survivors who have already regained a high degree of joint functionality. This is because the games are designed for able bodied users without accessibility in mind. By altering the game design to rely on less exerting movements would increase the number of users who are able to play. One instance of this is in Kinect Sports Bowling where the player is required to hold their arm out to the side to pick up a ball. This is a difficult move and not possible for a large number of stroke survivors especially during rehabilitation. Providing alternative ways to perform these actions would allow people with less arm functionality to participate more fully.

ACKNOWLEDGMENTS

This work was funded by the NTU Vice Chancellor's Bursary Programme. We would also like to thank the Occupational Therapists from Nottingham University's Division of Rehabilitation and Ageing who took part in the study.

ABSTRACT

Intensive rehabilitation is important for stroke survivors but difficult to achieve due to limited access to rehabilitation therapy. We present a virtual reality rehabilitation system, Target Acquiring Exercise (TAGER), designed to supplement center-based rehabilitation therapy by providing engaging and personalized exercises. TAGER uses natural user interface devices, namely the Microsoft Kinect, Leap Motion and Myo armband, to track upper arm and body motion. Linear regression was applied to 3D user motion data using four popular forms of Fitts's law and each approach evaluated. While all four forms of Fitt's Law produced similar results and could model users adequately, it may be argued that a 3D tailored form provided the best fit. However, we propose that Fitts's Law may be more suitable as the basis of a more complex model to profile user performance. Evaluated by healthy users TAGER proved robust, with valuable lessons learned to inform future design. The majority of users enjoyed using the Leap Motion controller and VR Headset, the inclusion of visual cues shows a general improvement in target acquiring performance and that Fitts's Law can be used to linearly model user reaching and pointing movements in 3D environments. However, in some situations this is not the case, emphasizing the importance of user profiling to examine the user's kinematic behavior more intricately.

INTRODUCTION

Upper limb rehabilitation following a brain injury, stroke, or other condition affecting upper limb movement, is carried out by occupational therapists and physiotherapists to recover and adapt the patient's movement and improve activities of daily living (ADL). Research confirms that rehabilitation is capable of improving arm function during both the early and late phases of stroke. However, effective therapy must be intense and requires the repetitive practice of task-related movements and actions (1). Repetitive task training involves intensive repeated practice of appropriate functional tasks and is thought to reduce muscle weakness and form a physiological basis of motor learning (2).

Virtual reality (VR) has significant potential to support self-management of such rehabilitation, in that it allows individuals to interact and train within stimulating, realistic virtual environments. It provides users with the opportunity to practice intensive repetition of meaningful task-related activities necessary for effective rehabilitation (3). A recent Cochrane review of 12 trials involving 397 participants for the upper limb, stated that the use of VR and interactive video gaming might be beneficial in improving upper limb function and ADLs; when used as an adjunct to usual care or when compared with the same dose of conventional therapy (4). This Cochrane review concluded that it is unclear at present which characteristics of VR are most important. However, they emphasized the need for pilot studies assessing usability and validity as part of the development process if designing new VR programs for rehabilitation purposes; these studies may also afford insight on the key VR characteristics for retraining of movement e.g., in reach and pointing tasks.

In this chapter we expand on our latest research (5), presenting a multi-sensory VR system, Target Acquiring Exercise (TAGER), and evaluate its usability and performance for upper limb rehabilitation. We evaluate Fitts's law as the basis of an adaptive system to model movement performance for reach and touch tasks in a 3D virtual space. TAGER evolved from previous VR and augmented reality (AR) testbeds developed by our research group (6) and particularly from initial research undertaken with the Leap Motion controller (7). TAGER utilizes several natural user interface (NUI) devices to track the user, namely the Leap Motion, Microsoft Kinect V2, and the Myo armband, and affords the option of wearing a VR headset (in this experiment the Oculus Rift DK1). In the experiment outlined in this paper, the tasks comprise basic 3D reaching and pointing exercises so we can effectively evaluate the system and user model. The experiment reported here focused on testing with healthy users to help us evaluate the user interface ahead of planned experiments with impaired users, and has helped us refine the user profiling system. A participatory approach to system and experimental design was taken; engaging with physiotherapists and occupational therapists in local health trusts, namely the Regional Acquired Brain Injury Unit (Musgrave Hospital, Belfast), the Stroke Unit at the Royal Victoria Hospital (Belfast), and third sector agencies, e.g., Brain Injury Matters (Belfast).

A core interest in VR as a rehabilitation tool is due to its potential to provide an enjoyable experience. However, VR systems are flexible technologies supporting feedback, capability adaptation, high intensity, repetitive, functional exercises to encourage motor control and motor learning. There are an increasing number of studies mainly focused on using commercially available hardware devices to support upper limb rehabilitation (4). Recent cheaper, high-quality commercial technology, such as Leap Motion and the Myo, offer new

opportunities for effective, center and home based self-managed rehabilitation. When combined with other existing technology, they have the potential to improve accuracy and reliability of performance monitoring, although research utilising these technologies is still limited. Feedback is of particular importance to patients, and VR systems have the potential to excel in providing rich, informative, personalized, just-in-time responsive feedback. Feedback cues in VR environments, when appropriately designed, can help users improve interaction performance. Rehabilitation systems have implemented multi-modal cues such as visual, tactile and auditory cues. The organization of movement is related to the quality of the viewing environment, particularly visual cues between the user's arm and the objects to improve spatial awareness (8). Tactile cues have also been reported to improve motor performance (9), and are mainly used to help users verify a successful interaction. Positive auditory cues provide user motivation to perform intensified repetitive tasks, represent temporal and spatial information very well and can improve motor learning (10).

Adaptation is an important usability factor within a VR rehabilitation user interface design, to enable a system to adapt both to a diversity of motor control capabilities and as rehabilitation progresses (6). This capability to adapt is important as a user may become frustrated if the tasks are too difficult or bored if tasks are too easy; thus maintaining engagement is vital in rehabilitation. Techniques proposed in the literature for adaptive VR rehabilitation systems include fuzzy logic and Fitts's Law (11). Fitts's Law is well known in the user interface community and has also been applied within the stroke rehabilitation (12) context. Fitts's Law models a user's motor skills by predicting the time to reach and touch a target based on a target's size (W) and the distance (D) from an origin (Eq. 1). The logarithmic element of the equation, known as the "Index of Difficulty" (ID), is used to quantify the difficulty of reaching a particular target. Thus, the movement time (MT) required to acquire a target is linearly dependent on ID , where smaller and further away objects are harder to attain.

$$MT = a + b \log_2 \left(2 \frac{D}{W} \right) \quad (1)$$

Equation 1 shows Fitts's original equation, but other researchers have devised variations of the equation to provide an improved model in different situations. Two popular adaptations of Fitts's Law are Shannon/McKenzie (eq. 2) and Welford (eq. 3), which were originally tailored to quantifying human movement behavior for 1D and 2D tasks. They have also been applied to 3D environments, but recently new forms of the equation have been devised to represent 3D interactive movements more accurately. Equation 4 (13) adapts Shannon/McKenzie (eq. 2) to include the addition of a movement direction parameter, to account for the consideration that MT is also dependent on the user's angle of motion (θ) on the Y axis from the origin to a target.

$$MT = a + b \log_2 \left(\frac{D}{W} + 1 \right) \quad (2)$$

$$MT = a + b \log_2 \left(\frac{D}{W} + 0.5 \right) \quad (3)$$

$$MT = a + b \log_2 \left(\frac{D}{W} + 1 \right) + c \sin \theta \quad (4)$$

OUR STUDY

The research described in this chapter has an exploratory emphasis and focuses on investigating VR NUI design, particularly (i) the reliability of tracking systems and the modelling of user motion via Fitts's Law and its variants, (ii) the aesthetic design of multi-modal cues, and (iii) the usability and acceptability of the VR headset. The purpose of conducting this research – and the subsequent follow up with impaired users – is to ensure that the underlying interactive interface and adaptive motion tracking system is as robust as possible before adding further user interface elements, game components, and connected health systems. Ultimately our intention is that the system will be robust enough for unsupervised usage by stroke patients.

Participant Recruitment

Healthy participants were enrolled in the experiment from students and staff at Ulster University. Inclusion criteria included that participants should be 18 years old and over, have no vision issues (e.g., blurred vision, color distortion, light sensitivity, depth perception), nor any disability that affected the upper extremity. Participants completed a questionnaire to gather information regarding IT and gaming literacy and to determine inclusion in the experiment.

Target Acquiring Exercise (TAGER)

TAGER is a custom designed 3D pointing exercise for upper limb rehabilitation, designed based on requirements from research (14) and clinician involvement. TAGER utilizes a number of technologies that work together to monitor and provide feedback to users while completing upper arm rehabilitation tasks. The Leap Motion controller is a small desktop NUI which contains an infrared camera specifically design to track fingers, hands and arms. It tracks up to 20 bones per hand, with 150° field of view and approximately 8ft³ of 3D interactive space. TAGER uses the Leap Motion as the main interactive device within the virtual world for tracking motion and facilitating target acquisition. Microsoft's Kinect V2 is similar to the Leap Motion, though instead of sensing hands it senses motion of the human skeleton. We collect data of all joints in the upper body in motion with the goal in a future version of providing guidance on suitable functional task movements and other factors. It is natural for a person with an affected limb to move their whole body forward rather than extending their arm, especially if tired. As this would hinder improvement through the rehabilitation process, system feedback and guidance can be crucial. The Oculus Rift DK1 (VR Headset) contains a 7" screen with a resolution of 1280×800 (16:10 aspect ratio) and a 90° field of view and enables head positional and rotational tracking. User head motion controls the viewpoint within a virtual world. The Oculus is investigated in this experiment to determine if it is acceptable for use and could potentially be used to increase spatial awareness. The Myo armband slides onto a forearm, and uses electromyography (EMG) technology with eight medical grade EMG nodes attached, that read electrical signals from

the muscles. The Myo armband also includes an accelerometer and gyroscope to track movement and orientation on the forearm. The use of the Myo armband here is to collect data to be stored for future studies helping identify changes in muscles, which could highlight factors such as fatigue and correctness of exercise. The Myo armband also includes tactile feedback capability, for example, vibrations on the skin, which are used to introduce tactile cues into the system.

Experimental Setup

The experimental process comprised three stages: (i) a training stage which gives the participant ten minutes to familiarize themselves with the technology and practice interaction. The training tasks are very similar to the real trials. Through system testing and observing users before the actual experiment it was decided that ten minutes training would be sufficient time for the participant to familiarize themselves but not cause fatigue. After training, the patients are given a short two minutes' rest period before the next stage (ii), which is the complete TAGER trial. In stage 3, after each user completes the trial, a short discussion takes place gathering any comments the participant might have and for the investigator to ask questions related to the user's experience of the system. Throughout the experiment, the participant was closely monitored by the investigator who provided assistance if any problems arose. The experiment was strictly controlled; the location of each trial was always the same as was the equipment used. Equipment arrangement was identical for each patient ensuring no other possible variables could affect the collected results. Figure 1 illustrates the layout of the environment.

TAGER's 3D virtual environment is the inside of a basic walled room (no wall at the front) with a large start button on its floor. The user was prompted to push the button with their virtual hand to begin. An icosahedron shape was purposely chosen as the target object for its geometric properties, especially since visual cues are required to enhance spatial awareness. With changes in viewing angles, objects with a greater number of faces and edges such as icosahedrons, provide more clarity of visual cues (15). Each repetition (4 per level) contains 27 icosahedrons to target, all at different locations, a total of 108 per level (4×27). When the start button was pushed a single icosahedron appears randomly at any of the 27 locations. The user moves their virtual hand around the 3D environment touching each icosahedron that appears. When touched, the icosahedron disappeared, and another icosahedron appears on the floor of the room at the location of the start button. We call this object the origin; this approach was used to provide consistent movement trajectories. All objects were intentionally placed at fixed locations and at fixed distances from the user's view to simplify analysis.

The TAGER VR software for this research was constructed with ten levels; the first and last levels were identical enabling us to compare performance over the period of the session – considering learning and fatigue effects. All other levels were unique concerning scene attributes such as target object scale, multi-modal cues and VR headset use; to investigate the impact they had on user movement behavior (see Figure 2). Levels 2-9 were randomized per user to eliminate potential bias in the ordering; a rest period provided between each level and repetition. The unique levels comprise different combinations of scene attributes such as shadowing and proximity color change for visual cueing. Tactile cues were included using the

Myo Armband where a vibration was sent to the user’s arm upon successful target acquisition. We also changed the scale of the objects; objects were sized accordingly as 2, 3.5 and 5cm. Objects were scaled to discover the impact it has on cues. For example, larger objects were expected to give greater clarity to visual cues and thus quicker arm kinematics. These scene attributes helped build knowledge on the impact they have on arm kinematics, spatial awareness, movement speed and accuracy.

Figure 1. The Experiment setup showing the equipment locations and typical user interactions.

RESULTS

The above experiment was undertaken to investigate core aspects of TAGER. Data was recorded every tenth of a second from all input devices, and *MT* calculated and recorded to file automatically from tasks for analysis of the movement models. Of the 26 participants, three were excluded from data analysis due to missing data or system issues (loss of tracking).

Usability

Of the 26 participants, 77% reported that their experience using the VR headset was enjoyable, no motion sickness or other health-related effects were reported. 43% of people commented that they perceived their performance to have improved while wearing the headset, while 50% said that they needed time to adjust when first wearing the headset. We compared user performance between the VR headset and monitor use, with and without cues. We used a paired t-test to determine significant differences between users' average *MT* and found no significant difference between Cues ($T=1.681$; $DOF=21$; $p=0.053$) or No Cues ($T=1.591$; $DOF=21$; $p=0.063$). Though, there was a consistently slower user response when using the headset (Table 1). In other words, the participant's subjective experience was at odds with the objective measurement. Although this is not a significant issue so long as the effect is consistent among users, it is a consideration for future interaction design. Discussion with health professionals reinforced the importance of aesthetic cues in rehabilitation VR system design. We provided feedback on target proximity and acquisition through lighting and shading, as well as vibration from the Myo armband. Figure 3 shows variation in interaction difficulty with cues (C) or without cues (NC) for different sized objects (large – LRG, medium – MED and small – SML). While results were generally as expected – i.e., cues supported improved efficiency in target acquisition. It was not clear that cues improve performance for MED cue acquisition and more investigation is required. More detail will be covered on the effect of cues in the next sub-section.

**Table 1. The mean movement time comparing VR headset and PC monitor:
Cues(C), No cues (NC)**

Exercise	VR (NC)	Monitor (NC)	VR (C)	Monitor (C)
Mean MT (ms)	1174.2	1107.4	1165.0	1115.4
T-test P=(0.05)	0.063		0.053	

Figure 2. TAGER's level layout and scene attributes.

An objective way to evaluate system feature effectiveness in TAGER is to record target acquisitions (hits) against movement times. A target has been successfully acquired when the user's hand collides with the surface of the target object without leaving the Leap Motion's detection area. Hits are classified as unsuccessful when the user's hand leaves the boundaries of the Leap Motion's detection area before hitting the target; users were required to return to within the boundaries to hit the target. Users could not progress until they acquired the current target, even after registering an unsuccessful hit. It was found that targets positioned at the center depth (relative to the user) were more successfully acquired – a mean of 29 successful hits per task over all participants (Front = 22, Back = 26). Closer objects appear to have been harder to attain, suggesting we may need to consider moving the minimum distance further away (along the z-axis) or move objects closer to the z-axis along the x and y-axes. The latter suggests a cone area (16) for object placement – with the cone pointing towards the user – rather than a cuboid (which maps well to the Leap Motion's detection area). This approach might account better for arm kinematic differences in attaining targets in close and far locations. Users attained targets in all sectors with reasonable success, though on average there were 31 (28%) unsuccessful acquisitions per level from a total of 108 targets. This may be considered to be quite high for healthy users; if the Leap Motion was mounted on the VR headset, changing position so that the leap camera is pointing forward (user's facing direction) could possibly provide a more natural interactive space, and reduce unsuccessful acquisitions. TAGER's experimental design implemented two identical levels one at the beginning and end of the experiment, enabling investigation of the potential learning effects indicated by improved performance or user fatigue resulting in performance decline. The mean completion times for all users for the start task was 1257.8ms while for end tasks the mean completion time was 1081.4ms suggesting that, despite having 10 minutes training time at the beginning, user performance significantly improved over the experiment ($T=4.60$, $DOF=21$, $p=7.7E-05$). There are also some indications of fatigue (or loss of concentration) among several users. Analysis of experimental data in the next section enabled us to investigate the intricacy of user profiles.

Model Effectiveness

As outlined earlier we recorded user motion data in reaching from an origin to touch an object target at various distances. Figure 4 shows the lines fitted to the data through regression for four well-known forms of Fitts's Law.

Figure 3. The variation of interaction difficulty arranged by the magnitude of the mean movement time.

(4)	247.7	273.1	275.1	290.5	282.1	261.7	318.5	324.1	322.9	236.2	283.2 ± 32.7	3.5

Tables 2 and 3 show the average regression values of the y-intercept and slope values for all participants. Murata's 3D equation (4) provides y-intercept values ranging from 196 to 363, which are more representative of human movement response (typically 200 to 300ms); it also provided a more gradual gradient giving a more appropriate model of *MT* against *ID* (17). Thus, while all four equations provided similar results, we focused on Murata for further analysis. Figure 5 shows typical results while wearing the VR Headset with and without cues for medium sized targets and Murata's 3D form of Fitts's law. In Figure 5 when cues are included, user 1023 seems to improve her performance shown by a more gradual slope (decrease in value), the y-intercept (reaction time) towards a better representation of the typical human reaction time values and R^2 correlations are very similar. This experiment was fundamentally exploratory in nature. We used Fitts's law and linear regression to develop a user model, which will help us understand how best to create an adaptive system that can personalize interactive tasks. Table 4 provides user profiles from a proposed model comprising parameters such as regression line data, statistics on the residuals of the line fit, task performance and user information. Considering the explicit performance metrics (hits, movement times), target hits provided an informative statistic, and capable users are readily distinguishable from less able. Only one person had a score of less than 500 /1080 with the lowest score 472. The highest score was 900, and the average score was 754.74. Mean successful hits per person rose from 73.91 at the start to 77.22 at the end from a total of 108. The mean percentage improvement in hits over the experiment was 6.92% illustrating diversity of learning and fatigue effects among participants. The mean percentage reduction in *MT* was 13.79%. The average change in line fit according to R^2 and associated values were not significant (due to the spread of data values there are several valid lines). Change in hits between the start and end tasks in the experiment were potentially revealing of a possible learning effect (improvement) or mental/physical fatigue. A learning effect provided a challenge to adapting task difficulty per user – it is preferable to adapt difficulty based on Fitts's law only after the learning effect stabilizes. Nonetheless, it was helpful to identify that a user remains in a learning phase so that additional support can be provided. However, *MT* and hits should not be considered independently, as some users may slow down deliberately to improve hit performance. The mean slope gradient decreased by 26.85% and the mean intercept decreased by 29.82%. Shallower slopes indicated a more skilled response as there is less difference between acquiring close and far objects, while a rise in the intercept value moves the intercept closer to physiological reflex norms (generally between 200 and 300ms). Additional user profile information can be gained from the residual statistics of regression lines and the changes between start and end tasks. Mean standard deviation dropped by 19.28% and mean variance also fell by 32.49%, suggesting that on average users were becoming more accurate. Range dropped by 10%, supporting this proposal. Kurtosis of residuals increased by over six times the magnitude (positive values) suggesting an increased number of data points with a small deviation from the regression line. On the other hand, skew also increased 44.4% (also positive), which after examining the regression graphs of users we believe was due to users overshooting the target position and having to change direction. From our results, we did not identify a strong relationship between performance and user age or gender.

Data from seven of the twenty-three participants provided a poor fit to the model based on start task motion data. Data after the end session from five participants had a poor regression fit, though two of these participants were different from the seven identified from the start data. These two people may have been overly tired or bored, rather than being less capable, highlighting the need for intricacy and careful analysis of the profiles. To consider this further it was necessary to examine a few representative individual user profiles (Table 4). User 1026 was an informative example, who started well with a strong profile but whose hits and mean MT declined significantly during the end task. Despite having residual statistics during the end task that show less variability (indicating more effective target acquisition for a significant number of targets), hit score actually decreased, while skew and kurtosis both increased (suggesting more overshooting of the target), and R^2 and the associated P-value suggested an unreliable regression fit (possibly due to an increase in outliers). 1026's mean MT dropped by a 23.96%, which suggested, considering the user profile, that during the end task this user may have adopted a high-risk strategy. This is in contrast to 1019, who appeared to have become more conservative, and by moving slower (13.64% increase in mean MT) improved their hit score by 12.82%. This considered approach by user 1019 and other participants seemed to improve the likelihood that the user motion data corresponds to Fitts's law (and variants). User 1002 had the weakest start having the lowest number of hits in the initial task but improved hit performance by 50% and mean MT by 31.59%. However, even by the end task, this user's motion could not be applied to Fitts's law reliably, and they had less than a 50% hit success rate in the final task. User 1023 exhibited arguably the most sustained success, having the highest overall hit success and start and end scores of 90 and 91 respectively and overall an improved profile (based on regression values). As with user 1019, 1023 was not particularly fast but improved speed during the experiment. Three participants got slower over the experiment and all of these achieved higher scores in doing so. Five participants got lower hit scores and all of these, but one had much less adequate regression fit and three of these exhibited faster mean MTs. Further investigation is required to understand whether users with these profiles exhibit a decline of interest – the tasks were repetitive and several of these participants were quite skilled at the tasks – or due to mental/physical fatigue.

DISCUSSION

In this paper, we presented an initial version of the TAGER VR upper arm stroke rehabilitation system, which utilizes several inexpensive, commercially available input devices and a VR headset. We reported on an experiment that focused on the usability of the system and the use of various forms of Fitts's law to linearly model user motion - movement time against an index of difficulty – for reach and touch tasks in a 3D environment using a Leap Motion controller as an input device. Most users enjoyed using the Leap Motion device and perceived tasks to be easier with the VR headset on. No motion sickness or other negative health-related effects were reported. The importance of cues has been reported widely in the literature, and while our results show a general improvement in object acquisition with visual cues, we found the impact on targeting medium sized objects to be unclear. We outlined results from fitting user motion data to four forms of Fitts's law with each of the equations

exhibiting a similar success. Examining the statistics of the regression process based on Fitts's law we found that these equations could be used to linearly model user motion with the Leap Motion controller in a range of setups including the utilization of a VR headset. However, the data point variance across the regressed line was quite high, and Fitts's law should not be applied as a simple linear model of user motion equally to all users. We recommend that a form of Fitts's law, for example, Murata's 3D version could be used as part of an intelligent system to profile users. Although the motion of most users could be modelled effectively using Fitts's law, we found a few users who found the NUI so difficult that they could not be modelled linearly. Most of these users required more training than we expected but in some cases, users appeared to become tired or bored. A more complex profiling system will help to identify training requirements and distinguish between loss of interest and mental or physical fatigue. We intend to develop the profiling system with further experiments and subsequently investigate the system with impaired users.

Figure 5. Murata's 3D model of movement for user 1023 while wearing the VR headset, plotting Index of Difficulty against the user's response time to successfully target medium sized objects. Depth (z-axis) is distinguished by 3 locations in the virtual world relative to the user: front (red diamonds), center (green squares), and back (purple crosses).

ABSTRACT

After stroke, sustained hand rehabilitation training is required for continuous improvement and maintenance of distal function. An ideal home-based telerehabilitation system has to be low cost, easy to set up, effective in motivating the user to use it every day, generate progress reports to the user for self-tracking, and provide daily monitoring to remote clinicians. In this chapter, we present a system designed and implemented in our lab: the NJIT Home-based Virtual Rehabilitation System (NJIT HoVRS). A single subject proof of concept study was conducted and demonstrated that this system is easy to access and effective in motivating subjects to train at home.

INTRODUCTION

Stroke remains the leading cause of serious, long-term disability in the United States, with over 6.8 million stroke survivors (1). Although the incidence of death from stroke has been decreasing due to new medical treatments during the acute episode, this still leaves a significant number of individuals permanently disabled. Only 10% of survivors recover

* Correspondence: Qinyin Qiu, PhD, Department of Rehabilitation and Movement Sciences, Rutgers University, 65 Bergen Street, Newark, NJ, United States. Email: qiuqinyin@gmail.com.

completely, the majority have a long-term or lifelong need for help to perform activities of daily living and require further rehabilitation (2) as a result of a significant brain injury. Deficits in motor control affect the stroke survivors' capacity for independent living and economic self-sufficiency. The impact of even mild to moderate deficits in hand control in particular, affect many activities of daily living.

Intensity and progression have been proposed as key factors in successful stroke rehabilitation. A very recent article, offering a theoretical framework with which to develop future post-stroke clinical trials, proposed that intensity and progression are the active ingredients of a rehabilitation program that drive neural plasticity and lead to positive functional outcomes (3). Studies have shown that sustained hand rehabilitation training is important for continuous improvement and maintenance of function (4, 5). If the amount of therapy is critical to rehabilitation, our current institutional limitations undermine the probabilities for successful outcomes. Time constraints and expensive personnel as well as the restricted length of stay in both acute care hospitals and rehabilitation restrain the provision of an adequate dose of training for persons with stroke. After discharge from the inpatient stay, access to rehabilitation therapy can be difficult for some patients. This is due in part to inadequate insurance, lack of transportation, and the patient's dependence on their caregiver. Having access to long-term rehabilitation training anywhere and at any time is necessary for sub-acute and chronic patients to continuously improve their functional abilities. There is a momentum building for increased attention to the development of technological interventions intended to support repetitive on-going home-based practice for better recovery of upper extremity motor function.

Innovative telerehabilitation systems have been developed using information and communication technologies to provide rehabilitation services at a distance. Many studies have developed video-game driven systems from commercially available gaming consoles such as Wii and Microsoft Kinect (6). Other groups have examined the use of custom-made tele-rehabilitation systems (7, 8). Most of these systems target arm or postural control, and require more space than may be available in the patient's home. These systems do not address hand rehabilitation. There is a vital need to explore intensive home-based upper extremity interventions that focus on the hand. An ideal home-based telerehabilitation system has to be low cost, easy to setup, able to motivate the user to use it every day, generate progress reports to the user for self-tracking, and provide daily monitoring to remote clinicians. Exciting new technologies have now made this approach possible and hold promise for long-term benefit. These technological advances - for the first time - allow for virtual reality simulations interfaced with discrete finger and hand tracking that is affordable and easy to use.

The NJIT Home-based Virtual Rehabilitation System (NJIT HoVRS) integrates the Leap Motion Controller and virtual reality technology to provide focused rehabilitation of wrist, hand, and finger movement. This paper presents the design concepts behind the NJIT HoVRS and the results of a proof of concept test. We believe that the NJIT HoVRS is a powerful tool that will give patients access to affordable, effective, and long-term rehabilitation in their home, allowing them to maximize and sustain stroke recovery, while increasing their overall quality of life.

SYSTEM DESIGN

NJIT HoVRS has two sub-systems to deliver home-based training: 1) a patient based platform to provide the training and 2) a server based online data logging and reporting system. In the patient's home, a cross platform virtual reality training application runs video games (developed in the Unity 3D game engine using the language C#) on their home computer. The Leap Motion Controller (LMC) infrared tracking device is used to capture motion of the hand and arm movement without requiring wearable sensors that may be difficult to put on independently or could potentially restrain movement.

Hardware

The Leap Motion Controller (LMC) (see Figure 1) is a \$50 computer hardware sensor that captures detailed hand movement as well as hand gestures. The heart of the device consists of two cameras and three infrared LEDs. A data validation study showed the LMC to be accurate and reliable as long as the target is within its visual area (± 250 mm of the LCM center) (9). The device's USB controller reads the sensor data into its own local memory and performs any necessary resolution adjustments. This data is then streamed via USB to the Leap Motion image API. From there, we programmed the system to feed tracking data into virtual reality activities by calling the Leap Motion API.

If the patient's arm is severely impaired and he/she cannot support the hand against gravity above the Leap Motion Controller, the Armon™ Edero, a spring compensation system, can be provided to the subject (see Figure 1). The Edero provides 12 different levels of passive support allowing it to accommodate a wide range of patient sizes and strength levels. It requires a single, setting that can be provided during the patient's initial evaluation. Minimal instruction is required to teach patients to readjust support levels on their own

Figure 1. Left: RAVR-Home architecture design. Upper right: Leap Motion Controller. Lower Right: Armon Edero™ arm support.

Fruit Picking, f. Fruit Catching, g. Car game, h. Hand Fly, i. Wrist Fly, j. Arm Fly, k. Piano, l. Breakout.

Software

A user-friendly GUI interface lists all of the training activities allowing patients to choose which activity they want to begin with using just one mouse click.

Currently twelve games have been developed, each one designed to focus on training a specific hand or arm movement such as wrist rotation or finger individuation (see Figure 2). An avatar is at the corner of all game environments to provide verbal praise and encouragement as therapists usually do in real world. Therapists configuration page can be enabled by pressing “T” for game condition pre-setup, such as work space size, game challenge level, etc (see Figure 3a). All games are downloadable via HoVRS website.

Maze: Player controls the movement of the virtual character through their hand location. The score is defined by the number of spheres the character intercepts along the maze path. The character falls if he deviates from the defined path. As the game level increases in difficulty; the platforms and bridges that the character is guided over become narrower and sharp turns become more frequent.

Whack-a-mole: The player controls the position of the hammer through arm movement in the horizontal plane. Rotation of the hammer is controlled by pronation/supination. Success score is defined by the amount of moles hit.

- Soccer goalie:** The player controls the position of the virtual hand to block the approaching soccer balls from hitting the goal.
- Bowling:** The player reaches forward and extends their fingers to apply force to the ball to knock over the pins.
- Fruit picking:** The player must reach and use a pinch movement with their thumb and forefinger to pick apples and oranges from trees and sort them into the correct basket to increase the score.
- Fruit catching:** To catch the fruit, the player controls location of a collection basket through horizontal arm movement. To increase the score, the player uses forearm pronation/supination to drop the collected fruit into a second basket. The frequency of falling fruit decreases when the player misses 25% of the falling fruit
- Car game:** The player practices opening and closing their hand to control the car speed. Closing the hand slows the car down allowing it to maneuver over speed bumps.
- Hand flying:** The plane speed is constant. The player controls vertical position of the plane by opening and closing their hand. Success score is defined by the number of floating spheres intercepted.
- Wrist flying:** The plane speed is constant. The player controls vertical position of the plane by changing the pitch of their hand at the wrist. Success score is defined by the number of floating spheres intercepted.
- Arm flying:** The plane speed is constant. The player controls the horizontal position and roll of the plane by moving their arm left and right and pronating/supinating their forearm. Success score is defined by the number of floating spheres intercepted.
- Piano:** The player plays a song by pressing the highlighted key with the indicated virtual finger. The amount of finger individuation required to successfully press any keys increases as the player progresses. However, it scales back down when they are unable to hit the key for 6 seconds.
- Breakout:** The paddle used to direct the ball follows the palm position of the player. The ball is directed by bouncing off the paddle and hitting the bricks above to clear the screen.

Figure 3. a. Therapist setup interface; b. Calibration interface; c. Hand not visible warning.

System Calibration and Hand Position Correction

A comprehensive calibration procedure (see Figure 3b) is used to measure each subject's active range of motion within the LMC visual area and this range is scaled to fit into the video game virtual environment. To create greater ease of use, games have been designed to display a red frame (see Figure 3c) to guide the subject back to the LMC visual area whenever his/her hand deviates from the calibrated range.

Data Collection

Performance and kinematic data collected during rehabilitation training using the NJIT HoVRS is securely transferred to Amazon Simple Storage Service (S3) at the end of the each training session for offline analysis. Patient data is automatically processed to produce daily progress reports. Therapists can securely access the reports through a password protected website, which will also host system updates.

SYSTEM VALIDATION

In order to evaluate NJIT HoVRS’ ease of use and reliability, a 45 year old female patient with moderate hemiparesis of the upper extremity (UEFMA = 45) due to a cortical stroke was recruited. She was a police detective prior to the stroke and was able to return to full time deskwork 6 months after the event. She lives alone but her family lives nearby and gave her a lot of support during her rehabilitation. She had little to no video game experience prior to this training. The system was placed in her home. Without help from the therapist or engineer, she successfully finished 7 thirty minutes training sessions utilizing all twelve of the games at least twice (Figure 4).

Figure 4. Exercise duration for each gaming activity over one month of therapy, as reported by the HoVRS website.

Car Simulation

As shown in Figure 5 (left panel), the subject was able to maintain her hand above the Leap Motion and control virtual car speed by opening and closing her hand. As the simulation went on, she gradually opened her hand more than she was capable of during the initial calibration.

Figure 5. Performance during a single session of Car (Left) and Maze (Right) simulations. Left panel: Two horizontal lines indicate maximum hand closing and opening during initial calibration. Arrow indicates moment when hand tracking was lost and the car speed dropped to zero. Right panel: Arrow indicates moment when the avatar fell off the maze plane and the game restarted at the beginning of the level.3

Maze Simulation

In the maze simulation (Figure 5, right panel), after successfully reaching the target, the subject will advance to a higher level that requires more hand stability. If the subject fails to reach the target, the score collected from the current level will be deducted and the subject starts again from the beginning of the current level. As shown in Figure 5 right, our subject was able to successfully pass the first four easy levels. However, as difficulty level increased, the subject started to slow down and make multiple attempts to complete fifth level.

Questionnaire

In a post-training questionnaire, the subject noted the system's ease of use and a desire to incorporate the system as part of her on-going therapy. Subject felt that this therapy system was engaging. In her comments, she said that the system is easy to use, and she almost forgot that she was participating in rehabilitation training while she was focusing on trying to complete the computer tasks. Her arm was tired after doing the training, but not her hand. She felt this system would improve her hand motion. She wished it could have been part of her original therapy and wanted it to be part of her on-going therapy. Subject said most of the games were engaging. She was able to understand the requirements and learn how to play them quickly. The easiest game for her was the Car simulation because it had a one-dimensional control requiring only hand opening and closing to manipulate the car's speed. Her favorite game was the Arm Flying simulation because its soothing music made her relax and enjoy the training. The most difficult game for her was the piano because it required both arm stability and finger individuation. The most confusing game was Whack-A-Mole because different lighting and random appearance of the moles provided too much information and caused confusion about how to proceed. The most non-intuitive game was Soccer Goalie because the orientation of the virtual hand and the real hand did not match. The virtual hand displayed in the virtual environment was vertical with the palm facing forward, while the real hand was horizontal with the palm facing down.

Figure 6. Therapist can monitor subject's daily progress via HoVRS website. Plot shows the sum of distances between the palm and five fingertips.

System Server for Data Monitoring and Visualization

All training data could be accessed remotely from the data server via HoVRS website. The therapist can access daily training data of a specific subject for a specific game activity via website. As shown in Figure 6, therapist chose to display daily maximum hand opening value from game GestureFly on website. The therapist sent a short text messages to the patient whenever there was new training data shown on the server side as a way to praise her effort and encourage continued participation. The data showed that repeated performance of several simulations resulted in increased finger opening as measured by the system.

DISCUSSION

We intend to bring a “wellness” approach to the achievement of independent upper extremity manipulation and function for people post-stroke. The National Wellness Institute (mailto: <http://www.nationalwellness.org>) encourages “a conscious, self-directed and evolving process of achieving full potential.” Through the development of an easy to use and engaging home-based virtual reality exercise program we modeled the wellness concept of continual self-directed exercise to allow people with hand and upper extremity motor deficits to achieve their full potential. NJIT HoVRS is a low cost, easy to setup, reliable and engaging home-based hand rehabilitation system. Virtual reality simulations are engaging and the subject was motivated to play them for a long period of time. Currently, there is little available for home-based hand therapy (10). The advantage of this home-based system is its focus on hand-based simulations. Our objective was to provide markerless hand tracking (LEAP) and simple support of arm motion in 3-dimensional space to allow the patient to move freely, while it helps them keep their hands over the LEAP’s effective range. Clear online directions, delivered visually and aurally through imaginative avatars allow the individuals to practice independently. Novel algorithms provide safe and effective interactions with the serious games. Despite this complexity, the use of novel technologies makes this affordable system easy to use. Compliance with home-based exercise programs is low. We believe strongly that the NJIT-HoVRS home-based system will effectively deal with compliance issues through the engaging games, the easy to use system (no donning and doffing difficulties), the enticing encouraging avatars, the success algorithms and the instant availability of daily achievement graphs. This self-paced, independent home practice is consistent with a “wellness” approach that should empower stroke survivors to take an active self-directed approach to their rehabilitation.

ABSTRACT

Each year 152,000 people in the United Kingdom have a stroke. Almost all have an initial facial weakness. Many resolve in the first few days but it is estimated that 26,000 people experience some kind of long-term paralysis in their face. A survey of 107 United Kingdom based clinicians found that routine treatment of facial weakness was provision of exercises with a written instruction sheet. A multidisciplinary team, which includes patients, researchers and therapists have produced a working prototype system to improve facial weakness. It is called Face to Face and includes a Kinect sensor, a small form PC and a monitor. Patients follow exercises given by a therapist on the screen; the system records and simultaneously gives feedback, with a facial recognition algorithm providing tracking data for each captured frame of the user's face. Results from our small clinical trial indicate that the system is more successful at getting patients to complete their

exercises than using a mirror, patients liked it, and they said it had helped improve their facial symmetry. Therapists said Face to Face encouraged patients to exercise daily, they liked the fact that it could be individually programmed and could record how much the patient had exercised. Based on the initial project work and positive outcomes Face to Face aims to help patients practice their facial muscle exercises to speed their recovery, providing direct benefits in terms of costs and time, and offering patients significant improvements.

INTRODUCTION

The overall aim of the project was to test an effective, engaging and affordable interactive facial exercise system for use with people with facial weakness following stroke. This is to meet patient and clinical needs and lead to measurable improvements in clinical outcomes (1-3).

Face to Face is a computer based system that enhances and automates the therapy provided by Speech and Language Therapists (SLTs). The system is initially aimed at stroke survivors suffering from facial paralysis, particularly with stroke patients suffering from swallowing and speech problems. The project development team also propose that the system may become a 'platform' system and be adapted and used more widely for a number of conditions and associated facial weakness.

A partnership between Nottingham Trent University, Nottingham CityCare Partnership, University of Nottingham, an industrial partner and service users within the UK have produced a system for use in the home, which uses the Microsoft Kinect games interface and a PC monitor to develop an interactive system to assist in the rehabilitation of patients with facial weakness. The aim is that patients will use this system to complete exercise programmes by copying on-screen exercises, and as they do this the system will monitor and *measure* the patient's face. Members of the University of Nottingham Stroke Research Partnership Group confirm the need for facial paralysis rehabilitation; currently there is a lack of appropriate and affordable alternatives in the market.

The system recognises facial expressions by tracking movement across the face and applying the recognised motion onto an onscreen representation of the user. This tool recognises differences between an undesirable one sided (unilateral) movement and a desired symmetrical movement across both sides of the face. This information is then conveyed via the monitor using the form of a graphical representation of the patients face. Using the representation as both a visual and auditory communicator, the system takes the patient through a series of exercises and indicates the degree of success with the exercise programme. An international patent application for the system was filed in 2015 (4).

Patient Benefit

A key aspect of the system is the ability to visualise the improvements that the patient is making from repeated exercises. The system is simple to set up, with no need to attach any systems or markers to the face. The user interface permits small bursts of exercises to be performed throughout the day, rather than undertaking one long and tiring session. The

overall aim of the initial project study was to test an effective, engaging and affordable interactive facial exercise system for use with people with facial weakness following stroke. This is to meet patient and clinical needs and lead to measurable improvements in clinical outcomes. The system has the potential to be of benefit to patients by: improving fidelity in rehabilitative exercises prescribed for facial weakness; providing immediate feedback to patients on their progress; improving patient's facial weakness, including carers in the rehabilitation process (a Stroke Association recommendation); assisting patients in meeting the recommended target of 45 minutes daily therapy and reducing the need for patients to visit hospital for rehabilitation.

Clinical Need

Approximately 16% of people suffering stroke have long lasting facial weakness (5). A combination of physiotherapy, occupational therapy and speech therapy has been proven to be clinically effective in the treatment of those who have suffered facial weakness following a Stroke. However, whereas the National Clinical Guideline for Stroke (6) indicates that patients should receive 45 minutes of therapeutic treatment daily, the majority of patients receive far less than this. The Royal College of Physicians National Sentinel Stroke Clinical Audit (7) states that only 33% of patients receive 45 minutes or more physiotherapy daily and only 18% of patients receive 45 minutes or more speech and language therapy daily.

It is clear from previous studies, and from involvement with partners at Nottingham University Hospital and the Stroke Association, that there are currently insufficient resources within the NHS to provide the necessary level of therapeutic care post Stroke. The most common rehabilitative exercises prescribed to facial weakness sufferers are either practising motions in front of a mirror or using an instructional DVD. These methods cannot be considered as engaging, due to their lack of feedback and quantifiable progression. Less commonly available is an electrical muscle stimulator designed for facial uses. This machine is made by the NHS electronics departments, and is in short supply, with recipients tending to get a maximum of six weeks to use the system before it is given to the next patient. The machine electrically stimulates the affected muscles to the point that they get exercise through contraction. It is reported to work well in the short term, but owing to short supply and the high price of working machines, along with a lot of training required on the part of the user, it is not currently considered a sustainable solution.

Initial System Concepts

Initial system design concepts were based on the utilisation of the patient's own TV with a 'plug and play' 3D system attached. Over a development period of 18 months the preferred options were discussed and agreed with the patient and public involvement group (PPI), resulting in a PPI informed user interface and physical system design based on the Kinect sensor as shown in Figure 1.

Figure 1. Initial concept (inset) and PPI informed system design.

The system that has been developed as a result of this project recognises facial expressions by tracking movement across the face and applying the recognised motion onto an onscreen representation of the user. How the user performs a series of facial exercises is assessed by the system and scored according to how well the user can do each of a defined set of expressions. The therapist is provided with a record of exercises as they were performed. New movements can be introduced automatically, with incrementally achievable goals throughout the week. The system will enable shorter consultations through the presentation of quantified improvement and empower the carer and the stroke survivors to take on some of the role of supervising the performance of the exercises.

It is proposed that the ‘home rehabilitation’ solution would help offset some of the problems associated with transfer from hospital to home care. The “Moving On” report (8) states that 48% of Stroke survivors believed that community and home-based therapy helped them become less long term reliant on carers.

System Overview

Game based technology platforms are now widely used for physical rehabilitation of patients, recognised as a potential motivational tool for rehabilitation. New opportunities in rehabilitation have clearly arisen with emerging technologies of computer games and novel input sensors including 3D cameras. Hossein and Khademi (9) provided a review on the technical and clinical impact of the Kinect on physical therapy and rehabilitation. Omelina et al. (10) examined serious games for physical rehabilitation and Webster and Ozkan (11) provided a detailed review of elderly care and stroke rehabilitation systems utilising the Kinect. As 3D facial image processing for this research project provides clear additional pose mapping functionality, the benefits of processing depth information when compared to 2D vision systems was explored by González-Ortega et al. (12) in relation to Kinect based systems for cognitive rehabilitation exercise monitoring.

Currently the system has been developed utilising pre-existing facial recognition software known as Faceshift (available from www.faceshift.com and now owned by Apple). Image data is acquired from the Kinect and, when a face is detected, a model is generated of the user's face. A profile can be stored for each user by capturing a pre-set series of expression, with an increased level of accuracy obtained by placing markers on a scanned face. This setup routine may be performed typically by a speech and language therapist (SLT), but should only need to be carried out once, following which the user can operate the system independently.

OUR STUDY

A short review on image processing was conducted by Samsudin and Sundaraj (13) for facial paralysis and facial rehabilitation, identifying image processing as being widely utilised but with very limited applications in relation to facial rehabilitation. Further Xiaozheng and Gao (14) provided a critical review of face recognition techniques and the clear challenges particularly in relation to pose invariant face recognition, whilst Wang et al. (15) examined real time movement linked to an evaluation of skeletal pose tracking using the Microsoft Kinect first and second generation hardware.

Clearly various complications in computer vision require an assessment of pose objects in real-time with numerous reliable solutions available for pose estimation utilising feature-based 3D tracking. However difficulties can arise based on the need for fast and robust detection of known objects in view, for example the Kinect sensors used for this project were notably affected by ambient lighting conditions.

For the Face to Face system, once the facial recognition software is set up to track a user's face the facial recognition algorithm provides tracking data for each captured frame of a user's face. The tracking data relates to a number of facial gestures, together with a value associated with each gesture. In Faceshift, 48 channels of raw tracking data are provided per frame, each of which is associated with a number ranging between 0 and 1. The numbers, or scores, represent the strength of deformation on the 48 predefined gestural channels. For example, the gestural channel 'BrowsD_L' measures lowering of the left eyebrow, and 'LipsStretch_L' measures sideways movement of the left corner of the mouth. These numbers

do not represent physical units, but are relative scores defined by upper and lower limits of each facial gesture. These scores are then used to analyse how well the user is performing a particular facial expression.

The speech and language therapist (SLT) defines a number of facial expressions, the facial expressions being specific to a user's rehabilitation programme. These facial expressions can each be defined as a combination of facial gestures that can be captured by the facial tracking algorithm, with each facial gesture having an associated target score. The overall aim of an exercise programme setup for a user is to encourage the user to perform the facial expressions and have these analysed and scored by the computer, using the facial recognition algorithm. To do this, a measure of how well the user is performing a particular facial expression needs to be defined. The mathematical space of tracking variables obtained from the facial recognition algorithm is mapped into a target space of facial gestures (or 'poses') for a particular facial expression. For each pose a measure termed a 'pose match strength' may be defined, for example as another number ranging between 0 and 1.

Pose match strength can be computed from the source tracking channels by defining a subset of the source channels as 'pose channels' that influence the pose match strength value for the facial expression being assessed. Source channels that are not included in a particular pose definition can either be ignored or treated as 'wildcards' for the match, for which any value will match. These represent channels that are irrelevant to the facial expression being exercised. As an example, mouth poses typically would not depend on eyebrow positions, resulting in the values for any eyebrow-related channels being discounted in an assessment of a mouth-related pose. Included pose channels may each define a target value or score for the pose, typically over the input range of between 0 and 1). This score is used to calculate an individual channel match value (again between 0 and 1). The range of input source channel values, i.e., from a minimum to a target value, is linearly mapped to an output pose channel match of 0 to 1. Beyond the target value the output pose channel match is capped at 1.

Figure 2 shows a pose tracking value over time, as defined by 14 successive samples, with a pose match peak of 0.8 and a peak value defined at 0.7 based on the development of the pose tracking value. During each 'out of pose' phase (while the system is looking for an 'in pose' event), whenever the instantaneous tracking value reaches a new highest value this 'pose match peak' value is recorded, and the time is recorded. A moving average is then maintained over the 'time since last peak', which will start at the peak and gradually decline as the instantaneous match strength diminishes.

Once a predefined time threshold is reached (which may, for example be around 0.5 seconds, and typically less than one second) without a new peak value being observed, an enter pose event is triggered and the current moving average is stored as a match value for the current 'active' pose. Conversely if a new instantaneous peak value is reached before the time threshold is reached, a new peak value is recorded, the timer is reset, and a new moving average measurement begins. This can happen several times before reaching a stable peak, particularly if the signal is noisy and/or the peak value is relatively low. The partially unsuccessful short-duration peaks before the final successful peak are analogous to 'false horizons' that are due to noise in the signal, whereas the moving average represents an adaptive threshold which continually adjusts to varying user ability and tracking response.

Each pose channel included in the pose definition may be marked as either a goal or a constraint. The output pose match strength is a relative score that can be calculated as the maximum of the set of all computed goal pose channel match values, limited by the minimum

of the set of all constraint pose channel match values. This is similar to goal channels acting as logical ‘OR’ and constraint channels acting as logical ‘AND’. The score for each facial gesture may be defined as a ratio of a score for the facial gesture provided by the facial recognition algorithm to the target score for the facial gesture. The score may range between 0 and 1, and be limited to 1 if the ratio exceeds 1.

Figure 2. Pose tracking over time (samples 1 to 14).

FINDINGS

Each of the exercise types relies on a predefined series of steps, these steps are illustrated in Figure 3. The process begins with an on-screen instruction phase with an acknowledgement when the number of repetitions has been completed. In between these two phases, the exercise involves looking for a particular target pose at any given time, which may even apply in the case of speed exercises which involve alternating between two poses. When an exercise target pose begins, the state is initially ‘out of pose’ and the system waits for the user to enter the pose. Once in pose, the system waits for the pose match strength to drop below a predetermined threshold value.

The events of entering and exiting a current target pose can trigger different responses depending on the exercise type. For example, speed exercises may switch to an alternate pose on exiting a first pose, whereas range exercises tend to set an ‘anti-pose’ during a relax phase which the user must enter (for example open mouth, followed by closed mouth) before returning to the original target pose for the next repetition (open mouth). Once the user is in pose the user is instructed to hold for a set period, and once the set period elapses the process can then repeat if required or complete. The series of steps involved in performing an exercise transforms a continuous range of pose match strengths into a series of discrete states and state change events. The user interface indicates the number of repetitions, which then triggers the next instructional video (“open your mouth...” / “...and relax”).

A particular problem, however, arises when considering how to determine when a particular pose has been achieved, i.e., when the state should change from 'out of pose' to 'in pose'. This determination can be made because of a continuous assessment of the score for a facial expression that is the subject of the exercise.

Figure 3. Exercise steps.

Pose Example

The 'ee' pose may be defined by MouthSmile_L (left) and MouthSmile_R (right) as goal channels, each with a target value of 0.8, defining JawOpen as an inverted constraint channel with a target value of 0.5. The following two conditions then result:

Condition 1:

MouthSmile_L = 0.2 - goal match $0.2/0.8 = 0.25$

MouthSmile_R = 0.6 - goal match $0.6/0.8 = 0.75$

JawOpen = 0.3 - inverted constraint match = 1

(less than target 0.5, inverted, capped to 1)

Pose match strength = min (max (goal),

min (constraint)) = min (0.75, 1) = 0.75

Condition 2:

MouthSmile_L = 0.2 goal match $0.2/0.8 = 0.25$

MouthSmile_R = 0.6 - goal match $0.6/0.8 = 0.75$

JawOpen = 0.8 inverted constraint match = $(1 - 0.8) /$

$(1 - 0.5) = 0.2/0.5 = 0.40$

Pose match strength = min (max (goal),

min (constraint)) = min (0.75, 0.40) = 0.40

This example could be interpreted as: an 'ee' pose requiring MouthSmile Left OR Right, AND jaw mostly closed. In the second scenario, the pose match strength is reduced to 0.4 because the jaw constraint is infringed, limiting the overall output value. In more general terms, a relative score for each identified facial gesture in a facial expression is calculated as a

ratio of the score for each identified facial gesture to the corresponding target score for the facial gesture. The score for the facial expression can be calculated based on a maximum relative score for the facial gestures defining the facial expression. Other combinations of goals and constraints can also be determined, depending on the particular facial expression to be exercised and whether any particular constraints need to be considered. For example, a facial exercise regime may be made up from a set of nine different poses. These may be combined using 9 range exercises with 9 strength exercises and with 3 poses used in pairs in ‘fast’ and ‘slow’ versions to make up 6 speed exercises (AB, AC, BC x fast/slow), making a total of 24 exercises to be performed in the exercise regime. A therapist can then make a patient assessment, and simply enable or disable each exercise from this palette of 24 exercises to quickly construct a tailored exercise regime for that user. A screenshot pose is shown in Figure 4 and the patient progress screen in Figure 5.

Figure 4. Exercise pose screenshot with a graphical indication of the user's score (right) and exercise number (bottom right) overlaid on a picture of the user next to an image showing the pose to be performed. The pose indicated by a speech and language therapist (left).

Figure 5. System diary and progress screen.

DISCUSSION

Participants found the Face to Face system to be a user-friendly rehabilitation tool for facial weakness after stroke, usage indicated that all participants were motivated to use the system (16). All participants made a slight improvement from baseline assessment and the therapist observed that: there was possible synkinesis in one participant and there was no deterioration or worsening of this following use of Face to Face system; one participant's ability to speak improved which increased confidence; one participant's natural smile became almost symmetrical and reduced drooling and reduced numbness was reported by one participant, leading to positive comments.

The speech and language therapist (SLT) and all participants noted functional changes and detected clinical changes in the level of facial weakness subjectively. The SLT assessed the level of facial weakness using the Sunnybrook facial grading system (17, 18) and prescribed a treatment plan of facial exercises from the Face to Face programme.

Currently development is focused on transforming tracking data received from the facial recognition algorithm into pose match strengths against a combination of facial gestures, the system enables a straightforward means of constructing and performing an exercise regime. In addition, development of a complex and informative web-based interface for clinical evaluation of patient's use and performance against rehabilitation regimes has been created. This will provide real-time adherence data during rehabilitation and allow a personalised exercise plan to be adjusted remotely, at any time, depending on patient's actual exercise patterns and improvements.

Looking forward, there is a growing number of technologies coming to market that will benefit and enhance this product. Of particular interest is the *new* 3D camera technology launched by Intel. These 3D cameras use the same principles as the Kinect camera but are designed to be integrated into phones, tablets and laptops. Another important feature of the Intel cameras is that they have been specially designed to focus on facial recognition and tracking, this will provide an accurate and reliable facial tracking system for us to use. In contrast the Kinect system is designed for full body tracking, although the system can be used to track facial expressions it is not its primary function and therefore limits the effectiveness of the product and requires a payment for third party software licences.

In current practice, SLTs priorities are in assessing and planning the patient's therapy, and non-professional assistant practitioners (APs) are used on a day-to-day basis with the patient to monitor adherence to the program and assist the patient. We propose to extend the stored usage database to include a record of planned usage regimes for each patient, and to provide a visual comparison of actual usage against the planned regime in the web interface. This approach would allow an AP to interpret the live usage data in the web interface, identifying overuse or underuse of exercises without needing to involve an SLT in the first instance. The web-based interface would still be accessible to SLTs who could perform any further analysis they felt necessary, but they would now also be able to remotely adjust the exercise regime while the device was still in the patient's home. Further development of the product is required and to address other market opportunities, including: improving the user interface to address shortcomings identified in trials and research; improving the compactness and portability of the physical embodiment; strengthening the robustness and functionality of the system (for example in low light conditions); reducing unit cost and finally allowing for a

wider range of exercises, implying a more complex interface requirement to allow SLTs to set up systems for patients.

It is anticipated that this additional functionality would reduce the ongoing costs of deploying the final system within everyday healthcare practice, by reducing the required time from the SLT.

ACKNOWLEDGMENTS

The authors also gratefully acknowledge the invaluable support and contributions to the project from: Ossie Newell MBE, The stroke service (PPI) group, Adam Russell and Paul Watts (both previously based at Nottingham Trent University, UK), Patrick Hall at Maddison and Claire Wragg at NTU. The Face to Face project was funded by the NIHR Invention for Innovation Programme (i4i). STROKE DUE TO VASCULITIS IN ADULTS

David S. Younger*, MD, MPH, MS

Department of Neurology, Division of Neuroepidemiology, New York University School of Medicine, and the College of Global Public Health, New York University; and the Department of Health Policy and Management, School of Public Health, City University of New York, New York, NY, US

ABSTRACT

The vasculitides are diseases characterized by inflammation of blood vessels and inflammatory leukocytes in vessel walls. There is an increased propensity for ischemic stroke due to the compromise in vessel lumina and distal tissue ischemia, with hemorrhagic stroke and aneurysmal bleeding due to loss of vessel integrity.

INTRODUCTION

The vasculitides are diseases characterized by inflammation of blood vessels and inflammatory leukocytes in their walls. There is an increased propensity for ischemic stroke due to the loss of vascular integrity with stenosis of vessel lumina and distal tissue ischemia; and hemorrhagic stroke and aneurysmal bleeding due to loss of vessel integrity. The 2012 Revised Chapel Hill Consensus Conference (CHCC) [1] nomenclature provides systemic nosology and a categorization of primary and secondary vasculitides. Central nervous system (CNS) involvement and stroke both occur in the single-organ vasculitic (SOV) syndrome primary CNS vasculitis (PCNSV) [2], as well as, due to limited or multiorgan manifestations of primary systemic vasculitides [1].

PRIMARY CNS VASCULITIS

With several proposed diagnostic schemes for PCNSV over the years [3-5], the combination of clinical and histopathological findings derived from cerebral angiography and leptomeningeal and brain biopsy remains the recommended method of definite diagnosis [6]. This approach facilitates the identification of clinicopathologic subtypes with persistent focal deficits and stroke [2] or intracranial hemorrhage [7] from those with reversible cerebral vasoconstriction syndrome (RCVS) [8] that may mimic true vasculitis, but do not require cytotoxic therapy.

Torres and colleagues [9] did not find a significant correlation between brain and leptomeningeal tissue, and the results of cerebrospinal fluid (CSF), neuroimaging, surgical technique, biopsy characteristics, or preoperative immunosuppressive therapy in 9/79 (11%) patients with suspected CNS vasculitis studied between 2005 and 2013. Yet in nearly three-fold (30%) of patients undergoing biopsy, the investigators noted alternative diagnoses of cerebral amyloid angiopathy, encephalitis, demyelination, and lymphoma. Postoperative complications occurred in 16%, 4% of which were serious. The authors concluded that while brain biopsy remains an important diagnostic tool, however further studies are needed to establish the clinical variables associated with a positive yield, as well as the surgical techniques that are most likely to provide diagnostic results with the lowest complication risk.

Historically, Younger and colleagues [3] described four patients with granulomatous angiitis of the brain histopathologically manifesting necrotizing vasculitis of arteries and veins of varying caliber in conjunction with giant cells and epithelioid cells. These authors [3] noted non-focal symptoms of headache and mental change, followed by focal weakness, seizures, and fatal coma in all four patients. Focal weakness with a stroke onset was noted in two (Patient 1 and 3) of the four patients, Patient 1 had onset of lethargy, focal ptosis and hemiparesis had predominant anterior (ACA), middle (MCA), posterior cerebral artery (PCA) and basilar artery involvement at postmortem examination. Patient 3, who presented with hemiparesis, ataxia, and dysarthria, and found to have predominant small leptomeningeal artery and vein involvement. Altogether, 15% of 78 patients overall had focal weakness with stroke onset compared to 42% who presented with focal deficits during the course of the illness.

In the same year, 1988, Calabrese and Mallek [4] described eight patients with classic angiographic or histopathologic features of PCNSV or so called primary angiitis of the CNS (PACNS), and reviewed the literature of 40 literature cases. Patient 2 [9] who presented with the clinical diagnosis of isolated angiitis of the CNS (IACNS) defined by classical angiographic features, had a clinical onset of transient weakness that progressed to fixed hemiparesis, nonfluent aphasia, alexia, and agraphia with later stabilization after combination prednisone and cyclophosphamide therapy.

Birnbaum and colleagues [5] proposed changes to the criteria of Calabrese and Mallek [4] to include a definite diagnosis of PCNSV only after tissue biopsy confirmation, noting strokes or persistent deficits in less than 20% of patients at onset, and with only about 28% of symptoms overall related to large cerebral vessel involvement. Salvarani and co-workers [2] noted that persistent neurological deficit or stroke and headache were the commonest initial symptoms affecting 68% of 101 patients so studied with PCNSV defined by diagnostic criteria similar to those suggested earlier [4]. Cerebral infarction noted on magnetic resonance

imaging (MRI) of the brain in 53% of patients, were multiple in appearances in 85%, bilateral in 83%, and involved the cortex and subcortex in 63%. Overall, their appearance suggested large-artery, branch-artery or small-artery distributions. Intracranial hemorrhage was noted in 8% of patients, and gadolinium enhancement was found in a third of patients, a quarter of whom demonstrated gadolinium enhancement of the meninges.

Montefort and co-workers [10] described a 57-year-old man with brain-biopsy confirmed PCNSV and a 2-month history of right arm weakness and numbness superimposed on a history of left-sided headache and intermittent visual field loss. Brain MRI showed evidence of cortical infarction across more than one vascular territory with signal changes consistent with hemorrhage in the left basal ganglia and parieto-occipital lobe. There was angiographic evidence of irregular narrowing and aneurysmal dilatation of the left terminal carotid artery that stabilized without new areas of new infarction after treatment with intravenous pulsed cyclophosphamide and corticosteroids followed by azathioprine. The neuroimaging features of this patient are shown in Figures 1 to 4, as well as, in a similarly affected patient in Figures 5 and 6.

Figure 1. Primary CNS vasculitis. T₂-weighted MRI of the brain demonstrates left frontal and parieto-occipital lobe areas of infarction. Reproduced with permission from [10].

Figure 2. Primary CNS vasculitis. T₁-weighted MRI of the brain showed left basal ganglia hemorrhage. Reproduced with permission from [10].

Figure 3. Primary CNS vasculitis. T₁-weighted MRI of the brain demonstrates gyral enhancement after intravenous administration of gadolinium before treatment (A), that resolves after immunosuppressant therapy (B). Reproduced with permission from [10].

Figure 4. Primary CNS vasculitis. Cerebral angiography shows a sessile internal carotid artery aneurysm. Reproduced with permission from reference 10.

Figure 5. Primary CNS vasculitis. T₂-weighted MRI of the brain shows bilateral cerebellar hemispheric infarcts and abnormal signal hyperintensities before treatment (A) that resolve after immunosuppressant.

Figure 6. Primary CNS vasculitis. Cerebral angiography shows widespread vessel irregularity and beading.

PRIMARY LARGE VESSEL VASCULITIS

Giant cell arteritis (GCA) and Takayasu arteritis (TAK) are prototypical large vessel granulomatous vasculitides (LVV). They involve the aorta and its major branches however any size artery can be affected [1]. Imaging studies and fluorescein angiography studies have shown that ocular involvement in GCA can affect not only ophthalmic, but also medium caliber retinal arteries and multiple ciliary arteries and their smaller branches; blindness may result from not only LVV but also injury to smaller ophthalmic branches [1]. Whereas GCA has a predilection for branches of the carotid and vertebral arteries and an age of onset older than 50 years, there is often polymyalgia rheumatic. TAK involves proximal subclavian and carotid arteries with an onset of 40 years or less. Neuroimaging studies employing ultrasonography, high-resolution MRI, and ^{18}F fluorodeoxyglucose-positron emission tomography (FDG-PET) imaging are useful modalities to depict superficial cranial and extracranial vessels, and large vessel subclavian and aortic involvement in GCA and TAK [11].

CNS involvement in GCA, which results from thrombosis of the carotid and vertebral arteries rather intracranial arteritis, affects vessels that contain elastin, more specifically the

internal elastic lamina that is absent from intracranial vessels more than 5 millimeters beyond the point of dural perforation. Reich, colleagues [12], Gonzalez-Gay, and co-workers [13] summarized the literature pertaining to stroke and GCA. Reports of CNS involvement have erroneously attributed to intracranial GCA rather than PCNSV [14-16]. Hellenhorset and colleagues [17] noted CNS events including stroke in 7.4% of 175 patients with confirmed GCA, as well as, and one patient with massive cerebral hemorrhage, two with stroke, and six with occlusive disease of the aortic arch. Caselli and colleagues [18] noted transient ischemic attacks or stroke in 7% of 166 patients with biopsy-proven GCA, among whom four had events in the vertebrobasilar system, and eight affected the carotid arterial system. With approximately 30% of patients manifesting neurological findings, the commonest of which were neuropathies of the arms and legs according to Caselli and colleagues [18], Salvarani and colleagues [19] observed that transient ischemic attacks or stroke in the territory of the carotid or vertebrobasilar arteries were less common neurological findings.

Gonzalez-Gay and co-workers [13] ascertained the frequency of cerebrovascular accidents (CVA) in association with GCA among 239 patients in a multicenter retrospective analysis to assess the features, therapeutic response, and predictors of visual loss and CVA. Eight patients (3%) developed CVA, equally divided between the vertebrobasilar and carotid territories. Symptoms of vascular ischemia preceded onset of arteritis by a median of 1.5 months, and were more frequent in those with visual involvement, especially permanent visual loss. Two patients with vertebrobasilar stroke died within one month despite aggressive corticosteroid therapy. Stepwise logistical regression analysis revealed visual loss and jaw claudication as the predictors of CVA.

Kerr and colleagues [20] summarized the clinical, laboratory and treatment responses of 60 patients with TAK based upon the presence of symptoms and signs of ischemic, inflammatory large-vessel disease as well as supportive arteriographic findings, noting ten (17%) patients with either transient ischemic attacks or CVA, and carotid or vertebral artery disease, eight of whom corresponded to the neurological deficit. One of the remaining two had hypertension, whereas the other patient had isolated stenosis of the innominate artery. Riehl [21], and Riehl and Brown [22] reported the clinical and pathological features of six patients with TAK noting widespread arteritis that not only involved the aortic arch and its tributaries by clinical and angiographic studies, but many other medium-, and large-sizes vessels. One patient with TAK manifested clinical and histopathological evidence of CNS involvement. That patient, a 43-year-old woman who presented with rapidly disappearing blood pressure and complained of spells of progressively worsening dizziness and dimness of vision, died of severe congestive heart failure. At postmortem examination, there was severe stenosis of the distal aorta, thrombosis of an aortic arch graft with nearly complete obstruction of all the great vessels by granulomatous panarteritis, as well as vasculitic involvement of the proximal portion of the left MCA, both PCA arteries, and anterior third of the basilar artery. There was massive infarction of the left temporoparietal region, the left half of the midbrain, brain stem, and cerebellum.

PRIMARY MEDIUM VESSEL VASCULITIS

Polyarteritis nodosa (PAN) and Kawasaki disease (KD) are prototypical medium vessel vasculitides (MVV). Although any size of artery is affected in this category, PAN is

associated with necrotizing arteritis of medium or small arteries without glomerulonephritis or vasculitis in arterioles, capillaries, or venules; however, it is not associated with anti-neutrophilic cytoplasmic antibodies (ANCA) [1]. By contrast, KD is an infantile or childhood disorder that is associated with the mucocutaneous lymph node syndrome, predominantly affecting medium and small arteries, occasionally coronary, the aorta, and other large arteries [1].

Among early postmortem series of PAN, Middleton and McCarter [23] noted CNS involvement due to arteritic lesions in one (Patient 1) that consisted of an occasional small artery. Brain tissue was not examined in one patient (Patient 2) and was not mentioned in another (Patient 3). Kernohan and Woltman [24] summarized the clinicopathological aspects of adult PAN in six patients studied at postmortem examination, estimating CNS involvement associated with stroke in about 8% of cases, and a combination of acute and chronic lesions that correlated with known exacerbations. In three patients, the peripheral nervous system (PNS) was widely involved at onset and at postmortem examination in addition to systemic involvement typically sparing the CNS, while in one patient, the PNS and CNS was involved alone. That patient was a 32-year-old man with onset of left arm and leg hemisensory loss and headache that progressed to paralysis. At postmortem examination, there was marked thickening and near complete obliteration of the right MCA, less so on the left side, and obstruction of the right PCA by a recent thrombus, with a normal PCA on the left. Microscopic analysis showed subacute and chronic lesions of PAN.

According to Guillevin and co-workers [25], CNS involvement is rare but motor deficiencies, stroke and brain hemorrhages can occur as well as cognitive disturbances associated with abrupt memory loss and scattered T₂-weighted hyperintensities on brain MRI suggestive of cerebral vasculitis. CNS involvement including stroke was noted in 9.6% of 115 patients in the FVSG [26] with hepatitis B virus (HBV)-PAN between 1972 and 2002. The FVSG treatment protocol for HBV-PAN generally included cyclophosphamide, corticosteroids and plasma exchange (PE), alone or together, followed by vidarabine, interferon-alpha (INF- α), or lamivudine, depending upon the time of diagnosis and different treatment protocols available [27-29]. So treated, nine patients (9.7%) who achieved remission subsequently relapsed, one of whom died of stroke, although the relationship between PAN and stroke was not clearly established. A retrospective study of 348 adult patients registered in the FVSG [30] who satisfied criteria for the diagnosis of PAN between 1963 and 2005 noted CNS involvement including stroke in 4.6% of patients overall, with a relatively equivalent frequency among patients with and without HBV-related illness.

PRIMARY SMALL VESSEL VASCULITIS

Small vessel vasculitis affects intraparenchymal arteries, arterioles, capillaries, and venules, however medium-sized vessels and veins are also be involved [1]. Two major categories of SVV include ANCA-associated vasculitis (AAV) characterized by necrotizing vasculitis with few or no immune complex (IC) deposits predominantly affecting small arteries, arterioles, capillaries, and venules associated with myeloperoxidase (MPO) ANCA or proteinase 3 (PR3). Marked vessel wall deposits of immunoglobulin (Ig) and complement characterize immune complex vasculitides. Granulomatosis with polyangiitis (GPA)

(Wegener granulomatosis [WG] type), eosinophilic granulomatosis with polyangiitis (EGPA) [Churg-Strauss syndrome [CSS]], and microscopic polyangiitis (MPA) (microscopic polyarteritis) are prototypical AAV, while cryoglobulinemic vasculitis (CV), IgA vasculitis/Henoch-Schönlein purpura (IgAV/HSP), and hypocomplementemia urticarial vasculitis (HUV) associated with C1q antibodies comprise the IC vasculitides; HSP/IgAV is predominantly a disorder of childhood.

ANCA-ASSOCIATED VASCULITIS

Granulomatosis with Polyangiitis

GPA leads to necrotizing granulomatous inflammation of the upper and lower respiratory tracts associated with necrotizing vasculitis of small to medium arteries, arterioles, capillaries, veins, and venules together with glomerulonephritis [1]. Drachman [31] described a patient with one month of headache that awakened him from sleep followed by rhinitis, nasal obstruction, epistaxis, mononeuropathy multiplex, confusion and hypertension. Active arteritis and necrotizing granulomata were found in the brain but not in peripheral nerves. Based upon the observations in a single postmortem studied patient, cerebral involvement according to Drachman [31], depended upon a combination of four separate entities, 1) Frank vasculitis of larger arterial branches particularly over the surface of the brain as demonstrated in his patient report; 2) Ischemia in portions of the territory supplied by the affected vessels; 3) Subarachnoid hemorrhage and hypertensive encephalopathy evidenced by microscopic infarcts in close relation to arteries with fibrinoid impregnation of their walls; and 4) Meningeal infiltration by mononuclear cells. Nishino and colleagues [32] described neurological involvement in 34% of 324 consecutive patients with GPA at the Mayo Clinic between 1973 and 1991 classified according to the American College of Rheumatology (ACR) [33] that included peripheral neuropathy in 16% compared to cerebrovascular events in 4% at some time in the course of illness, however rarely if ever at presentation. Of five patients with presumed clinical vasculitis, cerebral angiography was negative in two. Of twelve patients studied at postmortem examination, findings of vasculitis were found in only two. Fauci and colleagues [34] noted nervous system involvement in 22% of 85 patients, 10 patients (12%) of whom had CNS involvement including strokes at some point in the illness although not specifically mentioned at presentation. Moore and co-workers [35] estimated the frequency of neurological abnormalities of GPA at 23% to 50%, citing possible mechanisms of neural dysfunction due to inflammation from primary sites, remote granuloma formation, and vasculitis. Drachman [31] opinioned that contiguous extension of necrotizing granulomas might account for 24% of all neurological complications including those of the CNS.

Extensive cerebral infarction in the territory of the bilateral ACA was ascertained in a 67-year-old man with frontal headache that preceded detection of a large midline frontal mass lesion on computed tomography (CT), and known biopsy-proven GPA and granulomatous vasculitis of the nasal cavity, liver and kidney. Postmortem examination showed cerebral infarction in the areas supplied by A2 branches of both ACA, with occlusion of large sized ACA vessels by organized mural thrombi, and fibrinoid necrosis in the arterial branches. There was similar vasculitis with multinucleated giant cells involving small arteries and veins

diffusely in the frontal region of the brain suggesting contiguous spread from granulomatous nasal cavity lesions. Hoffman and colleagues [36] retrospectively assessed 180 patients with GPA for 6 months to 24 years noting nervous system involvement in 23% of patients, including CNS involvement and stroke in 8% of patients. A prospective analysis of clinical, electrophysiologic, radiologic, and serologic data of 128 GPA patients over 19 months [37] noted CNS involvement in 7%, the latter including granulomatous infiltration of frontobasal cortex arising from adjacent paranasal sinus granulomas, cerebral vasculitis, stroke, vascular myelopathy, and meningeal granulomatosis.

Microscopic Polyangiitis

Microscopic polyangiitis is a necrotizing AAV vasculitis with few or no IC deposits and commonly associated glomerulonephritis without granulomatous inflammation [1]. Davson and colleagues [38] separated fourteen postmortem studied patients from 1934 to 1947 with MPA into two groups based upon the presence of severe widespread glomerular damage. Wainwright and Davson [39] described MPA among six post-mortem studied patients from 1947 to 1948, mentioned CNS involvement. However, neither paper [38, 39] recorded stroke or histopathologic evidence of brain involvement. Nor was there mention of patients with CNS involvement by Adu and co-workers [40] among 43 patients with renal histologic evidence of MPA. Savage and co-workers [41], who studied 34 patients with MPA, all of whom presented with clinical evidence of a systemic SVV predominantly affecting the skin and musculoskeletal system associated with focal necrotizing glomerulonephritis, cited CNS involvement at presentation in 18% of patients without specific mention of stroke. Serra and colleagues [42], who reported the presentation, histopathology and long-term outcome of 53 patients with MPO from 1965 to 1981, cited CNS involvement at presentation in 15% of patients, the findings of which included stroke, convulsions, headache, confusion and drowsiness. Guillevin and co-workers [43] who reported the clinical and laboratory findings in 85 patients from the FVSG with MPA from 1969 to 1995, noted CNS involvement in 11.8% of patients at presentation and in 3% of 29 patients who experienced a relapse; however, there was no specific mention of stroke. Gayraud and co-workers [44] analyzed four prospective trials that included 278 patients with PAN, MPA and EGPA from 1980 to 1993, that reported stroke occurrence that accounted for 85 deaths. Villiger and Guillevin [45], who reviewed several retrospective European patient cohorts [40-43, 46], cited CNS involvement that included subarachnoid hemorrhage, cerebrovascular disease, meningitis and diffuse brain injury. Ben Sassi and colleagues [47] described intracerebral hemorrhage secondary to necrotizing vasculitis that similarly involved the nerves and muscles, citing three additional patients with hemorrhagic stroke due to MPA [48-50]. Ahn and colleagues [51] studied 55 patients with MPA, 69% of whom demonstrated perinuclear ANCA by immunofluorescence (IF) or MPO ANCA-seropositivity, noting CNS involvement in 5 (9.1%), none of whom developed end-stage renal disease. and one of whom died at follow-up without known autopsy.

Eosinophilic Granulomatosis with Polyangiitis

EGPA is a necrotizing vasculitis involving small to medium vessels that differs from GPA by the presence of eosinophil-rich necrotizing granulomatous inflammation of the respiratory tract in association with asthma and eosinophilia, and ANCA seropositivity when glomerulonephritis is present [1]. Churg and Strauss [52] described the clinical and postmortem findings of thirteen patients with asthma, fever, and hypereosinophilia. This was accompanied by eosinophilic exudation, fibrinoid change, and granulomatous proliferation that constituted the so called allergic granuloma. The latter were found within vessels walls and extravascular connective tissue of major organ systems. CNS organ manifestations were described in 8 (61.5%) of patients, and the cause of death in 3 patients who sustained cerebral hemorrhage or subarachnoid hemorrhage. Chumbley and co-workers [53] described 30 asthmatic patients from the Mayo Clinic over the period from 1950 to 1974 with necrotizing vasculitis of small arteries and veins, extravascular granulomas and infiltration of vessels and perivascular tissue eosinophilia. Lanham and colleagues [54], who emphasized that the combination of necrotizing vasculitis, tissue infiltration by eosinophils and extravascular granulomas suggested by Churg and Strauss [52] occurred contemporaneously in only a minority of patients, and that such histological findings could be encountered in other granulomatous, vasculitic and eosinophilic disorders in the absence of clinical asthma, allergic rhinitis, sinusitis, pulmonary infiltrates, and cardiac involvement pathognomonic of EGPA, noted CNS involvement in 25% of cases. Cerebral hemorrhage and infarction as a consequence of vasculitis or hypertension was a major cause of morbidity and mortality, accounting for 16% of deaths.

Sehgal and colleagues [55] noted neurological involvement among 14 patients with the clinical diagnosis of EGPA, three of whom had cerebral infarction two to fifteen years after initial diagnosis. The first patient was a 68-year-old woman with a stroke involving the territory of the MCA manifested as hemiparesis and aphasia. The second patient was a 34-year-old man with a right parietal lobe infarction pursuant to embolization of a left ventricular thrombus, manifested incoordination and hemisensory loss of the arm. The third patient was a 62-year-old woman with a thalamic infarction who manifested hemibody sensory loss. Guillevin and co-workers [56] studied 96 patients with EGPA between 1963 and 1995, noting ischemic stroke onset in 6 (6%) by brain computed tomography (CT). Mouthon and colleagues [57], reported 38 patients with EGPA from 1978 to 1998, citing CNS involvement in 3 elderly patients (7.9%) in whom CNS vasculitis was suggested by MRI of the brain in only one patient. Among 383 patients with EGPA enrolled in the FVSG Cohort [58] employing the definition of the ACR [59], CNS involvement was noted in 20 (5.2%) of patients at onset, with two-fold greater frequency of ANCA-seropositive serology than those ANCA-seronegative, but no specific mention of stroke frequency.

IMMUNE COMPLEX VASCULITIS

Cryoglobulinemic Vasculitis

Cryoglobulinemic vasculitis (CV) or CryoVas is typified by cryoglobulinemic IC deposited along small vessels predominantly arterioles, capillaries, veins, and venules in

association with serum cryoglobulins. In mixed cryoglobulinemia (MC), the immune complex is composed of IgM and polyclonal IgG with rheumatoid factor activity often in association with hepatitis C virus (HCV) infection. Disease manifestations of cryoglobulinemia was noted in 206 of 443 (47%) patients [60] that included palpable purpura, 12 (6%) of whom had CNS involvement; HCV Infection was the main etiologic factor noted overall in 75% of the 443 patients. A concomitant autoimmune disorder was noted in 24%, hematologic disease in 7%, and essential cryoglobulinemia in 11% of the patients overall. The original patient described by Lerner [61], a 56-year-old man who presented with chest pain, purpuric rash and a cold precipitating serum protein, did not have symptoms or postmortem findings referable to the nervous system. Marshall [62] noted widespread cerebral purpura with hemorrhage ascribed to occlusion of small blood vessels by eosinophilic protein precipitates that correlated with the clinical presentation of progressively fatal coma.

Abramsky and Slavin [63] described three patients with MC and CNS involvement. The first was a 55-year-old woman with anarthria, hyperreflexia, bilateral Babinski signs and progressively fatal coma, who was later found at postmortem to have multiple thrombotic occlusions of small intracerebral blood vessels with adjacent foci of ischemia and marked demyelination. The second patient was a 50-year-old woman, who presented with a Wallenberg syndrome and was found to have MC with occlusion of the left posterior inferior artery at angiography. The third patient, a 50-year-old woman who presented with right hemiparesis and pyramidal signs, was found to have a cryoprecipitate and occlusion of the left MCA.

Gorevic and colleagues [64] summarized the clinical aspects of long-term followup of 40 patients with MC noting incidental CNS involvement at postmortem examination and a fatal stroke in another patient. Petty and co-workers [65] described a 35-year-old woman with type II cryoglobulinemia, headache, purpura, and seizures who was found to have multiple areas of T₂ and proton density signal abnormalities in the cerebral and cerebellar hemispheres, with a gyral pattern of enhancement in the cerebral cortex, a nodular pattern of enhancement in the cerebellum, and early cortical infarction on right frontal brain biopsy without vasculitis; cerebral angiography was normal. HCV RNA was detected by polymerase chain reaction (PCR). Ince and colleagues [66] described a patient with paranoid psychosis and MC who was found to have right basal ganglia hemorrhage and multifocal small vessel occlusions by amorphous bland protein plugs and abundant Russell bodies present in arterioles and venules with relative sparing of capillaries.

Stroke was the presenting feature of CNS involvement in MC among two patients with lacunar infarcts and associated subcortical white matter changes on brain MRI [67, 68], and in one patient with a temporal arteritis-like syndrome with associated ischemic cerebral infarction [69]. Cacoub and co-workers [70] compared the features of patients with HCV examined for systemic vasculitis manifestations of PAN or MC noting two patients with cerebral vasculitis in the former versus none in the latter. Cacoub and colleagues [68] described CNS involvement in three patients with HCV infection and MC, one of whom was found to have a hemorrhagic lesion of the external capsule in association with pontine T₂ hyperintensities and parietal lobe infarcts. A second patient had a hemorrhagic occipital lobe lesion in association with cerebellar infarction and abnormal periventricular hyperintensities. A third patient had abnormal white matter hyperintensities.

Ferri and colleagues [71] studied the demographic, clinical, serologic features and survival of 231 patients with MC seen between 1972 and 2001, noting widespread vasculitis involving small- to medium-sized arteries, capillaries and venules with two or more visceral organs including the kidney, gut, and lung, noting no CNS manifestations of MC with exception of focal dystonia during interferon treatment in one patient [71]. Filipini and colleagues [72] reported a 63-year-old woman with acute severe encephalopathy HCV-related MC, dysarthria and hemiplegia. Fragoso and co-workers [73] reported a 35-year-old woman with dysarthria, left facial and left limb hemiparesis and hemisensory loss with MC in whom MRI showed ischemic lesions in the tail of the right caudate nucleus, corona radiata and posteromedial putamen. Casato and co-workers [74] reported the CNS findings in 40 patients with HCV-related CV in a multicenter, case-control study using MRI and neuropsychological testing. Although none evidenced cerebral infarction, small white matter lesions were found in all HCV-related MC subjects, a higher mean number of white matter intensities compared to HCV and healthy controls.

Terrier and co-workers [75] analyzed the data of 242 patients registered in the CryoVas survey ascertaining CNS involvement in 5 (2%) patients without specifying whether stroke was encountered. Terrier and Cacoub [76] reviewed CNS findings in HCV-seronegative and seropositive MC in CryoVas noting 2 (0.7%) patients among the former with CNS involvement, compared to 9 (5%) patients in the latter group evidencing CNS involvement but without further mention as to presence of stroke in any of the patients.

Hypocomplementemic Urticarial Vasculitis/C1q

Hypocomplementemic urticarial vasculitis/C1q presents with recurrent attacks of erythematous, urticarial and hemorrhagic skin lesions lasting up to 24 hours at a time, associated with recurrent attacks of fever, joint swelling, and variable abdominal distress. Circulating hypocomplementemia and C1q antibodies are associated with necrotizing SVV in skin biopsy tissue affecting arterioles, capillaries, and venules [1]. Apart from orbital pseudotumor with ptosis, diplopia, and headache in one patient with HUV syndrome, there was no mention of CNS involvement or stroke in a review of 18 patients with HUV/C1q [77]. Nor was stroke mentioned in a review of four patients studied at postmortem examination with HUV/C1q [78]. Buck and colleagues [79] cited rare CNS manifestations in HUV/C1q including aseptic meningitis, pseudotumor cerebri, transverse myelitis but no mention of stroke or cerebral vasculitis. Grotz and colleagues [80] did not mention stroke or CNS vasculitis in a case report and review of the literature of HUV/C1q. In a review of HUV/C1q, Davies and Brewer [81] cited CNS involvement as “very rare”, attributing development of pseudotumor cerebri to vasculitis of the venous sinus system. Ludivico and colleagues [82] suggested that chronic pseudotumor cerebri in their patients was a diagnosis of exclusion and possibly related to chronic corticosteroid use, but did not cite patients with cerebral vasculitis or stroke.

DIRECT AND INDIRECT BENEFITS OF TRANSLINGUAL NEUROSTIMULATION TECHNOLOGY FOR NEUROREHABILITATION OF CHRONIC STROKE SYMPTOMS

Dafna Paltin, Yuri P. Danilov, PhD and Mitchell E. Tyler

Department of Kinesiology,
University of Wisconsin—Madison, WI, US

ABSTRACT

Objectives: The original feasibility study discussed within this manuscript aimed to evaluate the scope of applications for a novel neurorehabilitation intervention. This retrospective piece was composed several years after the completion of the study and focuses on two interesting subjects in particular whose opposing symptomatologies represent the vast spectrum of chronic symptoms after stroke. The present paper brings to light important observations from that initial study and considers possible applications of TLNS Technology for the future.

Materials and Methods: Participants (N = 5) enrolled into a 13-month clinical intervention comprised of three components; (1) translingual neurostimulation (TLNS) using the PoNSTM device, (2) targeted training, and (3) physical exercise. These components will be elaborated on later in the paper. For the first six months of the intervention the participants practiced all three components for one hour, twice daily. Following a thirty-day withdrawal period, participants resumed exercise, training, and device use for an additional six months. Measurements of observation included the Sensory Organization Test (SOT), Dynamic Gait Index (DGI), Timed Up and Go (TUG) test, Stroke Impact Scale (SIS), Dysarthria Impact Profile (DIP), and the Quick Inventory of Depressive Symptoms, Self-Report (QIDS-DR16).

Results: Two specific cases were selected because of their demonstrability that TLNS Technology, as a platform technology, is much wider than previously thought, thus opening more doors in the direction of integrative neuroscience and combination therapy.

Conclusion: We hypothesize that the beneficial effects observed resulted from lasting and cumulative neuroplastic changes (functional, synaptic, and neuronal) in the

brainstem and cerebellum at the cellular and neural network levels, elicited by powerful flow of neural impulses (spikes) from the tongue. The original feasibility study importantly breaks ground for scientific inquiry regarding the limits of rehabilitation and improvement of symptoms for individuals in the chronic stage of stroke recovery. The observations reported here present an opportunity for applications of a new non-invasive brain stimulation technique in the applied and rehabilitative neurosciences.

Keywords: neurostimulation; stroke; rehabilitation; case series; motor dysfunction; post-stroke

1. INTRODUCTION

In 2010 the Tactile Communication and Neurorehabilitation Laboratory (TCNL), at the University of Wisconsin, Madison, conducted a feasibility study ($n = 5$) with the goal of evaluating the scope of applications for a novel neurorehabilitative technique for treating the chronic symptoms of stroke: the combination of targeted training, physical exercise, and translingual neurostimulation (TLNS). This targeted training involved balance and gait training on a treadmill, which was administered by a licensed practitioner (physical therapist). Physical exercise referred to stretching, power, and movement control exercises, also under the guidance of a physical therapist. The physical exercise component can also be thought of as physical conditioning, whereas the targeted training focuses on the specific deficits of the participants—in this case balance, gait, and mobility rehabilitation. For participants with balance and vestibular disorder these tasks are quite challenging. The stimulation itself, administered by a small instrument called the Portable Neuromodulation Stimulator (PoNSTM) device, delivers electrical stimulation to the brain via cranial nerve endings in the tongue – hence, *translingual* neurostimulation (TLNS). This three-part intervention was developed in the early 2000's originally by the name of Cranial Nerve Non-Invasive Neuromodulation (CN-NINM). Previous studies [20, 21] showed that this intervention evoked changes in brain activation patterns on fMRI in response to optic flow stimulus in regions associated with movement, balance, and various integration networks.

The present paper will focus on the results from two of the five subjects who presented with opposing symptomatology because they represent the broad spectrum of chronic stroke symptoms. One of the participants presented with above-normal cognitive function but deficient balance and gait, while the other presented with normal physical condition yet suffered from severe emotional dysregulation and speech problems. While the three other subjects also demonstrated improvement, this discussion will focus on the two that we believe best demonstrate the breadth of applicability of the intervention. The purpose of showcasing these two individuals is to make two key points: firstly, that the same intervention, which was successful in recovering balance and gait for individuals with vestibular disorder [22, 23] and multiple sclerosis [24, 25] in previous studies, works equally well when applied to symptoms of chronic stroke. Secondly, many other symptoms were improved in addition to balance and gait, subsequently expanding the package of symptoms that can potentially be treated using TLNS Technology to include cognitive and emotional disorder.

The primary goal of the feasibility intervention was to recover balance, gait, and mobility. These specific cases, however, demonstrate that the potential for application of

TLNS Technology is much wider than previously thought, thus opening more doors in the direction of integrative neuroscience and combination therapy.

All participants, who were several years post-acute, completed a standard prescribed stroke rehabilitation program and were deemed maximally recovered by a medical professional prior to enrollment in this study. Improvements in balance, gait, and mobility were measured using the Sensory Organization Test (SOT), Dynamic Gait Index (DGI), and Timed Up and Go (TUG) test. Measures of cognitive and emotional recovery included the Stroke Impact Scale (SIS), Dysarthria Impact Profile (DIP), and the Quick Inventory of Depressive Symptoms, Self-Report (QIDS-DR16). Tables 1 and 2 illustrate the specific measures and percent improvement for participants #1 and #2, respectively.

2. RESEARCH DESIGN AND CONTEXT

For multiple years, the TCNL engaged in discovering possible solutions for sensory and motor disorders. The goal of TCNL's research is to enhance the rehabilitation process by improving upon existing therapies and developing new ones for conditions, which, in the past, had few or no options. This clinical, IRB approved study consisted of a 13-month intervention, comprised of three primary components; (1) translingual neurostimulation using the PoNSTM (Portable Neuromodulation Stimulator) device, (2) targeted training, and (3) physical exercise.

For the first six months of the intervention these individuals practiced all three components for one hour, twice daily, followed by a thirty-day withdrawal period, and an additional six months of resumed exercise, training, and device use. This intervention design is informed by an accumulating body of evidence on the positive and compounding effects of integrative, multi-modal therapy [1-5].

3. RESULTS

3.1. Direct Benefits of Physical Rehabilitation

3.1.1. Recovery of Balance

According to the National Council on Aging, falling is the leading cause of fatal injury and the most common cause of nonfatal trauma-related hospital admission among elderly adults, resulting in 2.8 million injuries treated annually in emergency departments. Recovery of motor coordination and balance can decrease this danger dramatically. We used the Sensory Organization Test (SOT) to quantitatively measure participants' ability to use visual, proprioceptive, and vestibular cues to maintain postural stability [6]. One subject (referred to as Subject 1) improved 20.97% from baseline to the end of the intervention, from *substantially impaired* (greater than one standard deviation below the mean) to *normal*. This qualifies as a significant change and is attributable to the effects of the rehabilitation intervention [7].

A tremendous amount of this improvement occurred in the first two weeks and then was maintained through the end of the intervention, with the exception of a slight performance

drop after washout. This supports a possible stimulation dependence and retention effect, discussed in a previous publication [8].

We attribute these changes to the intervention and TLNS specifically because, as previously stated, all subjects enrolled in the study were in the chronic phase of their recovery after having undergone classically prescribed interventions, and were deemed maximally recovered by medical professionals as part of the study’s inclusion standards., Participants reported experiencing increased abilities to perform activites such as shopping, housework and grooming as well as a renewed sense of independence as a result of balance recovery. Furthermore, all participants expressed increases in their capacity to work and participate in social activities.

Table 1. Direct Benefits of TLNS Intervention on Balance, Gait, and Mobility Rehabilitation

Participant 1	SOT	DGI	TUG	Strength	Hand Function	Mobility	ADL/IDL	Social Participation
Baseline	62	14	15.6	56.3	20	66.7	55	37.5
End of Intervention	75	23	10.7	75	75	88.9	75	90.6
Percent improvement	20.97	64.29	31.41	33.20	275	33.30	36.40	141.60

Table 1 depicts scores and percent improvement between baseline and the end of the intervention for subject 1 on measures of physical and vestibular rehabilitation. SOT, DGI, and TUG are separete measurement tools. Strength, Hand Function, Mobility, ADL/IDL, and Social Participation are subscores of the Stroke Impact Scale (SIS).

3.1.2. Gait Normalization

The Dynamic Gait Index (DGI) DGI was developed as a clinical tool to assess gait, balance, and falls risk. It evaluates not only usual steady-state walking but also gait during challenging tasks. Subject 1 recovered 64% from baseline on this measure, eventually reaching the ceiling of this test. At enrollment, this individual presented with a deficient walking score of 14, which is consistent with scores reported in prior research on chronic stroke [9]. Individuals with vestibular disorders who score 19 or less on the DGI are 2.58 times more likely to have reported falling in the previous six months [10]. However, after only two weeks of treatment this individual’s risk of falling was dramatically reduced, recovering to a score of 18.

This improvement was also maintained for several weeks before dipping when stimulation was removed; again demonstrating stimulation dependence during the brief washout period. Improvement on the DGI satisfied both the Minimal Detectable Change (MDC) [11] and the Minimally Clinically Important Difference (MCID) criterion [12].

Figure 1: Map of direct benefits of TLNS Technology captured from quantitative assessments, clinical evaluations, and participant feedback

3.1.3. Mobility Rehabilitation

The Times Up and Go (TUG) task is a measure, in seconds, of rising from a chair, walking in a loop, and sitting back down. This task enables the assessment of a participant's coordination and weight transfer, and is challenging for people with balance and vestibular deficits for obvious reasons. TUG time for Subject 1 decreased by 31%, evidencing that their ambulation, coordination, and balance significantly improved as a result of the intervention [13].

3.2. Indirect Benefits of Mental Rehabilitation

3.2.1. Recovery of Emotional Control

Emotional control was the primary concern of the other participant at the time of enrollment (referred to as Subject 2). Her self-reports included feelings of being out of control of her emotions; with frequent high and low mood swings. She was particularly perturbed by her unshakable depression, which had persisted since the time of her injury. To observe changes in depressive symptoms, TCNL used the 16-item Quick Inventory of Depressive Symptomatology (Self-Report) to track the development of her symptoms throughout the intervention. Study administrators did not anticipate the profoundly positive impact that TLNS intervention would have on her depression. In 33 weeks, her depression scores on the QIDS-SR16 decreased from "moderate depression" to "no depression." This was a change of 10 points, which is considered a clinically significant improvement [14-16].

Changes observed in the Emotional subscore of the Stroke Impact Scale (SIS) also contributed to the evaluation of indirect emotional benefits from Translingual Neurostimulation therapy. The Emotional subscore improved 13% within three months, more than two standard deviations above the mean [17]. Furthermore, this level of improvement was maintained for the remainder of the intervention.

Table 2. Indirect Benefits of TLNS Intervention on Speech and Emotion Rehabilitation

Participant 2	QIDS-SR16	DIP	Emotion	Communication	Social Participation	Total Recovery Scale
Baseline	12	123	83.3	71.4	62.5	70
End of Intervention	2	181	94.4	96.4	100	95
Percent Improvement	83.33	48.78	13.33	35.01	60.00	35.71

Table 2 displays scores and percent improvement, from baseline to the end of the intervention, for Subject 2 on measures of speech and emotional rehabilitation. QIDS-SR16 and DIP are separate measurement tools. Emotion, Communication, Social Participation, and Total Recovery Scale are subscores of the Stroke Impact Scale (SIS).

3.2.1. Speech Rehabilitation

Subject 2 also presented with severe dysarthria at the time of enrollment. Speech rehabilitation was monitored through the course of the intervention using the Dysarthria Impact Profile (DIP) [18]. The combination of stimulation and targeted training improved the individual’s performance 58% in the first twelve weeks; a robust change [19]. By the end of the intervention, the subject’s dysarthria recovered nearly 49% from baseline. Congruently, their Communication subscore improved 35% from baseline to a level within one standard deviation of the normal range [17]. The positive changes observed in the participant’s speech are an example of the effectiveness of the TLNS Technology. For the targeted training component of the intervention, subject 2 engaged in specific speech-rehabilitation exercises. Study leaders hypothesize that the degree of her speech recovery, from the chronic stage, may be a consequence of an amplification affect encouraged by the simulation. However, further research is necessary to explore the validity and mechanisms of this proposed interaction.

Figure 2: Map of indirect benefits of TLNS Technology gathered from qualitative assessments and participant journals

3.3. Participant Self-Reports

3.3.1. Renewed Quality of Life

Although perception of quality of life (QOL) is highly individualized, it is recognized that an individual's ability to perform Activities of Daily Life/Instrumental Activities of Daily Living (ADL/IADL) may increase their perceived QOL. To explore this line of inquiry, TCNL had subjects record daily journals about their experience and progress throughout the duration of the intervention. The goal of these journals was to gain insight into the potential benefits or losses of QOL related to the intervention. The themes of multiple self-reported improvements are summarized in Figure 3.

As anticipated, subjects' self-reports of improved QOL match the quantified subscores of the SIS test. For example, both subjects reported recovery of participation in social activities, usefulness within their families, and greater independence to perform household activities. Participation/Role Function—a domain of the SIS that would encompass those activities—recovered 60% for one of the participant—an improvement greater than two standard deviations above the mean—and 142% for the other participant (125% of that in the first six months). . These reports are highly encouraging and help to emphasize the importance of this research, specifically for populations who have little to no other options.

Figure 3 summarizes participant self-reported improvements from TLNS Technology

4. DISCUSSION AND CONCLUSION

Translingual Neurostimulation Technology combines the use of targeted therapy, physical exercise, and non-invasive neurostimulation—delivered directly to the tongue—to enhance natural recovery mechanisms. From this feasibility study we discovered that the effects of the tongue stimulation were more universal effect than expected or previously demonstrated. This study was TCNL's first attempt to provide proof of our concept that *many*

functions can improve with the correct exercise and stimulation. These results provide supporting evidence for major principle of the intervention: that the combination of targeted training and physical exercise with tongue stimulation has the capacity to recover a wide range of symptoms, even from the chronic stage of disease or injury. We entered into a new territory to rehabilitate speech and emotion, and we consider ourselves successful in achieving a positive effect.

The significant finding of this study was that the intervention could be applied to address multiple, diverging symptoms arising from the same disorder (i.e., stroke). The investigators hypothesize that the beneficial effects observed resulted from lasting and cumulative neuroplastic changes (functional, synaptic, and neuronal) in the brainstem and cerebellum on the cellular and neural network levels, elicited by powerful flow of neural impulses (spikes) from the tongue. This feasibility study importantly breaks ground for the scientific community regarding the limits of recoverability and improvement of symptoms for individuals in the chronic stage of their stroke recovery. These findings present a new non-invasive brain stimulation technique with applications in applied and rehabilitative neurosciences. . The results of this feasibility study breaks new ground for the scientific community regarding the limits of recoverability and improvement of symptoms for individuals in the chronic stage of their stroke recovery. Additional research is necessary to understand the potential mechanisms of these phenomena and to optimize efficiency of the intervention.

While it is generally recognized that physical rehabilitation alone has limits for the recovery of chronic symptoms after disease or injury, the limits of combined interventions are more contentious. The idea that TLNS intervention can have a greater or multiplicative effect compared to other forms of intervention (or other forms of combined intervention) remains a question for future research. Next, TCNL intends to compare the impact of TLNS Technology to that of other neurostimulation interventions (such as TMS and TDCS) and to physical interventions alone. The authors leave it to the next generation of investigators to compare the impact of TLNS Technology to that of other neurostimulation interventions (such as TMS and TDCS) and to physical interventions alone.

5. ACKNOWLEDGMENTS

This research was supported by the University of Wisconsin Foundation. All human subject participation was conducted under the approval and oversight of the University of Wisconsin—Madison Health Sciences IRB.

Chapter 105

REHABILITATION INTERVENTIONS FOR UPPER LIMB RECOVERY FOLLOWING STROKE

Trinidad Sentandreu-Maño*

Department of Physiotherapy, University of Valencia,
Valencia, Spain

ABSTRACT

The various treatments are rightly based on the premise that the problems arising following a stroke can be considered recoverable neurological conditions. Spontaneous recovery has its limits and for this reason certain strategies are employed with the aim of stimulating, modulating or controlling this process. Within the rehabilitation process, a fundamental role is played by physiotherapy, the objective of which in the stroke patient is focussed on maximizing the restoration of lost motor functions and re-learning the skills needed for activities of daily living, securing maximum functional capacity and preventing possible secondary complications. Impairment of the upper extremity is one of the most frequent consequences following stroke and it directly impacts on the patient's functioning and quality of life, which justifies the need for a neurorehabilitation treatment appropriate to the specific needs of each patient and based on scientific evidence. In this chapter the different therapeutic strategies used in the field of physiotherapy aimed at the recuperation of the upper limb after stroke are described. Referring to the current literature, the full range of techniques applied in the recovery of these patients is presented, from conventional treatments to emerging approaches and new technologies.

Keywords: stroke, neurorehabilitation, upper limb

INTRODUCTION

Many stroke survivors are left with impairment of the upper limb. Approximately 69% to 80% of these patients initially have upper limb impairments (Kimberley et al., 2004) and

* Corresponding Author's Email: trinidad.sentandreu@uv.es.

between 55% and 75% show significant residual deficiencies (Kowalczewski et al., 2007). Patients with hemiplegia after stroke often present impaired motor control and functional disability, such as flaccidity, muscle weakness, abnormal muscle tone, and uncoordinated response, among others (Chen and Shaw, 2006). Functions related to manual dexterity are impaired in a high percentage of patients between 3 and 6 months after the illness, and complete functional recovery of the hand has only been documented in between 5% and 20% of cases (Alon et al., 2007). Therefore, numerous rehabilitative strategies have been proposed in order to improve recovery in stroke patients as soon as possible.

The various treatments are rightly based on the premise that the problems arising following a stroke can be considered recoverable neurological conditions (Butefisch, 2004; Carr and Shepherd, 1989). This process of recuperation will depend on various factors such as the age of the patient, hemispheric dominance, premorbid intellectual level, time since the appearance of the lesion and its size, extent and aetiology, among other factors (Díaz et al., 2011). Spontaneous recovery has its limits and for this reason certain strategies are employed with the aim of stimulating, modulating or controlling this process (Bayón and Martínez, 2008). Within the rehabilitation process, a fundamental role is played by physiotherapy, the objective of which in the stroke patient is focussed on maximizing the restoration of lost motor functions and re-learning the skills needed for activities of daily living (ADL) (Cameirão et al., 2009), securing maximum functional capacity and preventing possible secondary complications (Stokes, 2001).

As Pollock et al. (2008) observe in their meta-analysis, a range of different post-stroke strategies exist, although the difficulty of defining specific therapeutic methods, the lack of appropriate measurements of the results, the multitude of variables which participate in the treatment process and the heterogeneity of the sample characteristics have presented problems in achieving a meaningful evaluation of the different treatments. The best strategies for the recovery of the upper limb are still unknown (Chen and Shaw, 2006; Yozbatiran et al., 2006), for despite the routine use in clinical practice of traditional methods like those described below, there is still insufficient evidence about these treatment approaches. Nor is there any evidence available to date that proves that any one physiotherapeutic method is better than any another (Kollen et al., 2009; Barreca et al., 2003). Nevertheless, certain studies have indicated that physiotherapy as a whole can be beneficial (Kwakkel et al., 1999; Feys et al., 1998). Specifically, early intervention can be better than late (Cifu et al., 1999), but even treatments applied belatedly result in benefits (Farmer et al., 2014).

The optimum treatment characteristics are unknown (Farmer et al., 2014), but reference has been made to the fact that elements such as intensive activity, repeated practice, task-oriented activity, active participation of the subject and cognitive stimulation are crucial in achieving results (Veerbeek et al., 2014; Timmermans et al., 2009; Bayón and Martínez, 2008; Alon et al., 2007; Chen and Shaw, 2006; Pomeroy and Tallis, 2002). The heterogeneity of the treatment parameters and the characteristics of the population make generalized recommendations difficult, so further investigation is needed in order to define more precisely criteria related to the population, the treatment, the comparison with other interventions and their results (Farmer et al., 2014). The evidence base for stroke rehabilitation continues to grow; this includes studies using neuro-imaging as well as studies of novel therapies which might influence stroke rehabilitation practice and policy in the future (IJzerman et al., 2009). Referring to the currently available literature, various physiotherapeutic treatments used to promote upper limb recovery in patients following stroke will now be detailed.

CONVENTIONAL NEUROLOGICAL TREATMENT

The main traditional physiotherapeutic methods used to improve impairment of the affected limb and to recover motor function for stroke patients have been based on neurophysiological theory or motor relearning (Chen and Shaw, 2006). This conventional rehabilitation mainly consists of the Bobath approach, the proprioceptive neuromuscular facilitation technique, the Brunnstrom approach and the motor relearning technique (Pollock et al., 2014; Oujamaa et al., 2009; Chen and Shaw, 2006; Pomeroy and Tallis, 2002; Sparkes, 2000).

The Bobath concept, also known as neurodevelopmental treatment (NDT), is the most popular technique for stroke rehabilitation (Chen and Shaw, 2006). This method seeks to normalize tone through techniques of inhibition and facilitation of correct movement by means of manipulation of the key points. Many authors have identified the problem of a lack of published theoretical evidence to support the Bobath concept (Sparkes, 2000). It has been pointed out that some physiotherapy given within a Bobath framework might have an immediate beneficial effect on conduction in the corticospinal pathway and the ability to control joint movement (Pomeroy and Tallis, 2002).

The proprioceptive neuromuscular facilitation technique employs techniques to facilitate normal patterns of movement, spirals and diagonals, with the objective of inducing generalized patterns and thus generating a balance between agonists and antagonists, which permits both postural and motor control.

The Brunnstrom approach is based on observations of movement recovery in a vast number of stroke patients. Brunnstrom identified six different motor recovery stages after stroke; each grade was based on the degree of motor ability of the affected limb (Chen and Shaw, 2006). This method employs associated reactions, tonic reflexes and the development of basic synergistic movements to facilitate normal movement.

Finally, the motor relearning technique described by Carr and Shepherd incorporates principles based on specific training in tasks, including the practice in isolation of impaired essential movements and their subsequent training in functional tasks and activities. The Bobath theory, aiming at restoring postural control as a prerequisite to repetitive task training in order to be as physiological as possible, is opposed to theories inspired by these authors on motor skill training where the training programme should focus on performing a functional task, regardless of the motor strategies used (Oujamaa et al., 2009).

The body of evidence in systematic reviews and meta-analyses shows that when comparing improvement of upper-limb motor control in response to therapy, the Bobath approach seems to be no more effective than the rest of the strategies named (Chen and Shaw, 2006). The same point is also made by Barreca et al. (2003), who add that NDT was not found to be superior to other types of interventions such as forced use and traditional rehabilitation functional training.

It has also been reported that these approaches are less effective when compared to focused interventions such as modified Constraint-Induced Movement Therapy (CIMT), bilateral arm training or strengthening when applied in a task-specific way (Veerbeek et al., 2014). In the same vein, Hatem et al. (2016) concluded that there is moderate to high-quality evidence indicating that Bobath therapy is similar or inferior to other rehabilitation approaches such as meaningful task-specific training, CIMT, ARM-basis training, motor

relearning programmes and movement science-based physiotherapy for treating upper limb motor impairment and disabilities in acute, subacute and chronic stroke patients. On the other hand, it should be pointed out that one moderate-quality randomized controlled trial (RCT) was reviewed which indicated that Bobath therapy might be useful in patients with spasticity (Wang et al., 2005).

Veerbeek et al. (2014) in their exhaustive meta-analysis dealing with NDT found strong evidence for equal effectiveness compared to other interventions for muscle strength of the arm and insufficient evidence for grip strength, muscle tone, brain activity, and extended ADL. Furthermore, the effect of more time spent in NDT was also investigated, indicating that NDT is equally as effective as augmented NDT for muscle strength, arm-hand activities, basic ADL, extended ADL, pain, handicap, and quality of life outcomes; and augmented NDT is beneficial for motor function and range of motion.

KINESITHERAPY

On many occasions kinesitherapy also plays a part in conventional physiotherapeutic protocols. It involves joint mobilization, strength training, stretching, hands-on therapy and specific exercises utilizing objects and equipment (Farmer et al., 2014; Veerbeek et al., 2014; Pollock et al., 2014).

Therapists use a variety of techniques to promote upper limb recovery following stroke; however, the details of what they do are unclear, are not well defined in studies, and they are used in various combinations (Winter et al., 2011). The small number of trials and the methodological limitations make it inappropriate to draw conclusions from the effectiveness of hands-on therapy techniques (Pollock et al., 2014; Winter et al., 2011). The limited evidence of benefits resulting from stretching, passive exercises and mobilization, when applied to the hemiplegic upper limb following stroke, merits further research (Winter et al., 2011).

Concerning stretching, Hatem et al. (2016) argued that there is moderate to high-quality evidence indicating that stretching is similar to control rehabilitation approaches for treating upper limb impairments and disabilities in subacute and chronic stroke.

The findings from the meta-analysis carried out by Harris and Eng (2010) provide evidence that strength training can improve function without increasing tone or pain in stroke patients. A positive outcome for strength training was found for grip strength and upper-limb function and no benefit in ADL. Furthermore, a significant effect for strength training on upper-limb function was found for trials including subjects with moderate and mild upper-limb motor impairment. The authors recommend that future RCTs investigate the intensity, frequency, and specificity of strength training required for improving performance in daily activities. Ada et al. (2006) also provide support for the use of strengthening training as a part of rehabilitation programmes after stroke. In contrast, the meta-analysis by Veerbeek et al. (2014) showed non-significant effect sizes for motor function, muscle strength, range of motion and pain in the case of strength exercises for the paretic arm.

Isokinetic muscle strengthening is another rehabilitation technique, although this is not often used in stroke patients. It uses computer-driven isokinetic dynamometers which allow training for muscle strength (Hatem et al., 2016). The review presented by Hammami et al.

(2012) included two studies on this kind of treatment related to upper extremity following stroke. There is no consensus on the type of contraction mode, on the muscles that should be trained and on the dosage regimen of training, and there are no studies that have investigated the effects of isokinetic strengthening of wrist and finger muscles. There is not sufficient evidence to claim the superiority of this technique over conventional strengthening exercises (Hattem et al., 2016). More RCTs are needed in order to assess their effectiveness especially concerning upper arm rehabilitation (Hammami et al., 2012).

THERAPEUTIC POSITIONING OF THE PARETIC ARM

Also described in the literature are techniques focused on the positioning of the paretic arm, either without the use of external devices or its immobilization or stabilization by means of splints, support by weights, bandages or other technical aids, with the aim of maintaining or augmenting the range of movement, preventing incorrect positions, inhibiting reflexes, reducing muscle tone and also reducing oedema and pain (Veerbeek et al., 2014; Pollock et al., 2014; Langhorne et al., 2009; Barreca et al., 2003).

Therapeutic positioning of the paretic arm, without the use of splints, with the purpose of maintaining range of motion and preventing harmful positions of the paretic arm was investigated by Veerbeek et al. (2014). A significant positive effect size was found for passive range of motion of shoulder external rotation and non-significant effect sizes were found for passive range of motion of shoulder internal rotation, external rotation contracture of the shoulder, pain at rest and while moving, and basic ADL.

Regarding shoulder supports, low-quality evidence derived from an out-of-date review (Ada et al., 2005) shows no benefit of shoulder-supporting devices on arm function, shoulder external rotation and contracture.

Borisova and Bohannon (2009) investigated the effectiveness of the positioning of the paretic shoulder following stroke. This meta-analysis failed to support the benefit of using these techniques in order to prevent or reduce shoulder external rotation range of motion impairments after stroke. The authors stated that future trials should assess the effectiveness of longer duration positioning and of intervention earlier in the recovery process. The effect of positioning on other shoulder movements and on other joints should also be investigated, as should the effect of positioning and the combination with other treatments.

There is insufficient evidence to support or refute the effectiveness of elbow orthoses and hand splinting (Pollock et al., 2014; Hijmans et al., 2004; Lanning and Herbert, 2003). Further research is required in this field for evidence-based prescriptions. Lanning and Herbert (2003) suggested that future RCTs should not only consider the effects of different splint designs but also consider the effects of the time period for which a splint is worn and the hand's position within the splint.

An up-to-date meta-analysis (Veerbeek et al., 2014) pointed out that the use of reflex-inhibiting positions or local immobilization of the wrist and hand by splints or plaster have no significant effect for passive range of motion, muscle tone and pain. These authors also added that supportive techniques or devices for the prevention or treatment of glenohumeral subluxation or hemiplegic shoulder pain did not show significant effects for motor function of the paretic arm or for pain.

BILATERAL ARM TRAINING

Bilateral arm training is another rehabilitation technique suggested for upper limb recovery following stroke (Pollock et al., 2014; Veerbeek et al., 2014; Timmermans et al., 2009; Oujamaa et al., 2009; Urton et al., 2007). During bilateral arm training, movement patterns or activities are performed with both hands simultaneously but independent from each other and can be cyclic (Verbeek et al., 2014). It can be performed with or without the assistance of an external device (Hattem et al., 2016).

Bilateral movement training validated by the meta-analysis of Stewart et al. (2006) does not appear clearly superior or even as efficient as the unilateral mode in some other studies. Various reasons could explain these divergent results, such as post-stroke delay, degree of motor impairment, type of bilateral movement training proposed and amount of movement repetitions (Oujamaa et al., 2009). The key point of this kind of intervention is interlimb coupling, which is thought to rebalance interhemispheric inhibition, activate the affected hemisphere, and improve motor control within the affected limb (Pollock et al., 2014), although at present the neurophysiological processes that support this rehabilitation approach are still not fully understood.

Coupar et al. (2010) concluded that there is insufficient good quality evidence to make recommendations about the effect of simultaneous bilateral training compared to placebo, no intervention or usual care, for improving arm function after stroke. On the other hand, van Delden et al. (2012) compared the effects of unilateral and bilateral training and they claim that unilateral and bilateral training are similarly effective; however, intervention success may depend on severity of upper limb paresis and time of intervention post-stroke.

Considering more recent evidence, the meta-analyses presented by Veerbeek et al. (2014) showed non-significant effect sizes for motor function of the paretic arm, muscle strength, arm-hand activities, self reported arm-hand use in daily life, and basic ADL. In the same vein, the systematic review by Hattem et al. (2016) furnished moderate to high-quality evidence that bilateral arm training is similar or inferior to unilateral arm training or to conventional treatment. These authors also argued that its effectiveness on spasticity is also demonstrated to be controversial, owing to the disparity in results.

BIOFEEDBACK

Biofeedback provides enhanced awareness of movement or function, with the goal of improving voluntary control of that movement or function. It can be associated with electromyography (EMG) which provides information about muscle activity detected through surface electrodes placed on the skin, and it is fed back to the patient via electrical activity displayed on a visual display unit or by an auditory signal (Pollock et al., 2014). This technique has also been used in upper limb recovery after stroke (Pollock et al., 2014; Brewer et al., 2013; Timmermans et al., 2009; Langhorne et al., 2009; Chen and Shaw, 2006; Barreca et al., 2003).

The use of EMG biofeedback was previously endorsed by Hiroaka (2001), who stated that EMG biofeedback has a large effect on restoring arm function in post-stroke patients. In relation to this, Molier et al. (2010) pointed out that feedback has an added value for stroke

rehabilitation, although it was not possible to find which factors and types of feedback are most necessary for a beneficial effect on motor activities and motor functions, due to the combination of multiple aspects and types of feedback in the reviewed studies. With regard to stroke phase, a recent meta-analysis (Wattchow et al., 2017) that investigated therapeutic interventions in improving upper limb function in the first 4 weeks following stroke, has recommended the supplementary use of biofeedback within the acute phase post-stroke.

In contrast, the meta-analyses by Veerbeek et al. (2014) on this topic resulted in non-significant effect sizes for motor function of the paretic arm, active range of motion, and arm-hand activities; and Woodford et al. (2007) pointed out the existence of low-quality evidence when EMG biofeedback is compared with standard physiotherapy.

SENSORY INTERVENTIONS

Other therapeutic strategies in the treatment of the upper limb include sensory interventions (Farmer et al., 2014; Veerbeek et al., 2014; Pollock et al., 2014). Movement and somatosensory awareness can be enhanced in several ways, including techniques such as sensory re-education, tactile kinaesthetic guiding, repetitive sensory practice or desensitisation. Sensory and positional awareness may be stimulated by passive or active-assisted movement, as well as by stimulatory techniques such as stroking and tapping (Pollock et al., 2014).

Different interventions or upper limb sensory impairment after stroke are available but there is insufficient evidence to support or refute their effectiveness in improving sensory impairment, upper limb function, or participants' functional status and participation (Doyle et al., 2010). Schabrun and Hillier (2009) demonstrated some support for the effectiveness of passive sensory training in relation to sensory impairment and motor function. However, empirical evidence for active sensory training is limited. The scarcity of good quality evidence available on the variety of sensory interventions and the clinical and methodological diversity between the studies requires higher quality research, where more well-designed, better reported studies of sensory rehabilitation are needed (Doyle et al., 2010; Schabrun and Hillier, 2009).

The analyses of one recent meta-analysis (Verbeek et al., 2014) showed significant positive effect sizes for somatosensory functions and muscle tone, but in contrast, it resulted in non-significant effect sizes for motor function of the paretic arm, muscle strength, pain, arm-hand activities, and basic ADL.

COGNITIVE SENSORY MOTOR TRAINING THERAPY

Among the various therapeutic interventions, it is also worth noting the Cognitive Therapeutic Exercise based on the neurocognitive rehabilitation theory described by Perfetti (1999). This method is based on an approach which uses cognitive strategies such as observation of actions, the motor imagery or imitation in therapeutic exercises, in conjunction with guided activation of attention or problem solving for the recovery of movement after stroke (Sallés, 2015).

Currently there is very little evidence available on this method (Hatem et al., 2016). Wongphaet et al. (2003) carried out a report of case studies concluding that cognitive sensory motor training therapy may be an effective method for improving upper extremity motor function in chronic stroke and patients, but further RCTs are required. On the other hand, the study by Chanudol et al. (2012) showed no difference between Perfetti's method and conventional occupational therapy with regards to hand and arm function after a stroke. Lee et al. (2015) claimed that application of cognitive exercise therapy was effective for upper limb function and quality of life in chronic stroke patients. Future research should focus on application of cognitive exercise therapy in diverse populations, and assess its clinical utilization. The most recent study, published by Sallés et al. (2017), argued that despite the lack of statistical significance, upper extremity movement deficits improved when this neurocognitive approach was performed. The authors also stated that a careful selection of the appropriate difficulty for each patient together with the guidance of a therapist in the cognitive and sensory processes allowed greater and more prolonged improvements, especially for the hand function. Finally, the feasibility of the proposed protocol facilitates further research to consolidate evidence of these findings.

PHYSICAL AGENTS

Reference must also be made to interventions with physical agents such as electrical current, both in the form of TENS (Transcutaneous Electrical Nerve Stimulation) with analgesic aims or for somatosensorial stimulation at the sensitive threshold, and also in its neuromuscular application stimulating a muscular contraction (Veerbeek et al., 2014; Pollock et al., 2014; Hayward et al., 2010; Oujamaa et al., 2009; Langhorne et al., 2009; Urton et al., 2007; Chen and Shaw, 2006; Barreca et al., 2003); and also the use of thermal agents (Veerbeek et al., 2014; Oujamaa et al., 2009; Chen and Shaw, 2006) like cold or heat.

In the first approach related to *electrotherapy*, the stimulation evokes a sensory reaction without muscle contraction. According to Hatem et al.'s review (2016) regarding sensory electrical stimulation, there is moderate-quality evidence that TENS as an adjuvant to rehabilitation treatment is superior to the rehabilitation treatment alone with regards to upper extremity impairments and disabilities. Spasticity seems to diminish with this technique. Moreover, TENS appears to be beneficial in the subacute and chronic post-stroke phase.

In the second approach, where a muscular contraction is provoked, known as neuromuscular electrical stimulation (NMES), several applications can be distinguished: cyclic NMES (without voluntary activity by the patient), sensor or electromyographic (EMG)-triggered NMES (activated voluntarily by the patient) and functional electrical stimulation (FES) (associated with the performance of functional tasks) (Sentandreu, 2017). In some of these cases, NMES treatment can be applied by orthosis

A few previous studies have directly compared electrical stimulation modalities, yet conclusive proof of their effects is still lacking (Hara, 2008). De Kroon and IJzerman (2008) and Boyaci et al. (2013) compared cyclic NMES and EMG-triggered NMES and no difference in outcomes was found. These findings contrast with other reviews (Chen and Shaw, 2006; de Kroon et al., 2005), which argued that electrical stimulation triggered by voluntary movement appear to be more beneficial than other NMES modes. It has been

hypothesized that the intention to execute a movement, along with peripheral activity, further reinforces plastic changes compared to cyclic stimulation (Quandt and Hummel, 2014). A recently published study (Wilson et al., 2016) that compared the effect of cyclic NMES, EMG-triggered NMES and sensory stimulation, concluded that all groups exhibited significant improvement of impairment and functional limitation in the upper limb, though there was no difference based on the type of electrical stimulation administered.

Different authors support the use of NMES (Wattchow et al., 2017; Hatem et al., 2016; Howlett et al., 2015; Nascimento et al., 2014) in the recovery of stroke patients. However, there are various points that are inconsistent. The most recent research on electrical stimulation and upper limb recovery focuses mainly on the most effective protocols by comparing different variables of the applied programmes (i.e., NMES modalities, stimulation parameters, electrode placement, etc.), the characteristics of the patients who can benefit most from this treatment, its effectiveness as a complement to other emerging therapies, and not only its effects locally but also its impact on the central nervous system (Sentandreu, 2017). Hatem et al. (2016) claimed that there was moderate-quality evidence that NMES in combination with rehabilitation is superior to the rehabilitation treatment alone with regards to upper extremity impairment. It seems not to be effective on upper extremity disabilities. The review by Eraifej et al. (2017) found a statistically significant benefit from FES applied within 2 months of stroke on the primary outcome of ADL. The supplementary use of electrical stimulation within the acute phase post-stroke also was supported by Wattchow et al. (2017).

On the contrary, there are authors who indicate that its effectiveness is not clear. Pollock et al. (2014) indicated low-quality evidence related to the effectiveness of electrical stimulation. For their meta-analyses, Veerbeek et al. (2014) divided electrostimulation into NMES, EMG-triggered NMES, and TENS, and they only found significant effects on the use of wrist and finger flexors and extensors for NMES, shoulder muscles for NMES and wrist and finger extensors for EMG-triggered NMES. The other modalities analyzed did not show differences. Some authors (Gu and Ran, 2016; Vadafar et al., 2015) pointed out that electrical stimulation could be used in order to prevent or reduce shoulder subluxation early after a stroke, yet findings did not support their efficacy for pain reduction, improvement in arm strength, movement, functional activity, and quality of life following a stroke.

In the case of *thermal agents*, further research is needed to establish a basis for this type of treatment and to permit the making of prescriptions based on evidence. The study by Chen et al. (2005) demonstrated significant effects on several aspects of sensory and motor functional improvement in acute stroke with lower motor stage or flaccid motor control of the upper limb. The authors posed a number of questions that should be clarified in the future such as the optimal intensity, the time course of thermal stimulation, and also the patients appropriate for this type of treatment (Chen and Shaw, 2006).

EMERGING APPROACHES

Among the emerging approaches, that are based on a supposed cortical reorganization and optimization of motor relearning, are included repetitive and task-specific training, CIMT and other interventions based on the hypothesis of mirror neurons and motor imagery.

Repetitive task training involves the repeated practice of functional tasks, combining elements of intensity of practice and functional relevance (French et al., 2016). It is a component of current physiotherapy approaches in stroke rehabilitation (Pollock et al., 2014; Timmermans et al., 2009; Langhorne et al., 2009; Barreca et al., 2003). Key components of skill acquisition, such as active cognitive involvement, functional relevance of the task and knowledge of results and performance, are hypothesised to enhance learning during repetitive task training (Pollock et al., 2014). On the other hand, *task-specific training*, also referred to as functional task training, involves practice of tasks relevant to daily life and it is often combined with other modalities, such as assistive technologies (Timmermans et al., 2009). Task-specific training may be carried out as a form of repetitive task training (Pollock et al., 2014).

A recent Cochrane review (French et al., 2016) pointed out that there is low-quality evidence of improvement in arm and hand function following repetitive task training of the upper limb, and effects appear to be sustained up to 6 months post treatment. The authors also added that adverse effects should be monitored if it is put into practice and that more intensive therapy (over 20 hours) does not seem to be more effective for the upper limb. The authors' recommendations highlight that future research should evaluate practical ways of delivering repetitive task training interventions and maintaining post-therapy functional gain beyond 6 months; and these trials also should check clinical effect and cost-effectiveness analysis, in addition to including quality of life outcomes.

In an updated version of the last-named review, Thomas et al. (2017) concluded that patients who receive repetitive task training may be more likely to improve upper limb function after treatment and maintain these improvements during the 6 months after treatment than patients receiving usual care. The authors' findings indicate that patients appear to benefit from repetitive task training regardless of the amount of task practice, type of intervention, or time since stroke. Further RCTs should focus on the type and amount of training, including ways of measuring the number of repetitions actually performed by subjects.

With regard to task-specific training, evidence was insufficient to obtain conclusions related to the effectiveness of reach-to-grasp exercise-related interventions (Pelton et al., 2012). The authors stated that what is needed is RCTs with sufficient power and standardised outcome measures for future meta-analysis that should detail functional performance and kinematic measures of hand and arm coordination. In a recent meta-analysis by Wattchow et al. (2017) where rehabilitation interventions for upper limb function within the acute phase post-stroke were studied, key findings included significant positive effects for task-specific training in the first 4 weeks following stroke.

CIMT as described by Taub et al. (2006) is the most complete application of the functional task paradigm that applies motor skill learning principles to stroke rehabilitation. Its specific strategy is to induce motor learning and neuroplasticity with intensive training intervals (Hattem et al., 2016). CIMT differs from forced-use in that it requires both functional training of the affected arm and immobilization of the patient's non-affected upper extremity. The original high-intensity protocol of CIMT is well defined, although later modified CIMT protocols have been described with lower dosage regimens. This therapy seems to have a significant effect on upper-limb recovery; however, the application is limited to stroke survivors who have some distal voluntary movement in the upper limb (Chen and Shaw, 2006), are highly motivated, free of severe cognitive disorders and not at risk of falling

(Oujamaa et al., 2009). The main challenge in applying the evidence of benefit from CIMIT is that the intervention is time-consuming and tiring, presenting major challenges to compliance (Langhorne et al., 2009).

Hatem et al. (2016) showed moderate-quality evidence that CIMIT is superior to conventional rehabilitation with regards to upper extremity impairments and disabilities. This intervention seems to be effective in the different phases of stroke and its effects may persist till 12 months after training. According to the authors, CIMIT, either in its original or modified design, can be recommended for stroke patients after 3 months and in patients with active hand movement. Pollock et al. (2014) also indicated moderate-quality evidence of CIMIT effectiveness on measures of upper limb function. Key findings by a recent meta-analysis (Wattchow et al., 2017) included significant positive effects for modified CIMIT within the acute phase post-stroke. According to Veerbeek et al. (2014), significant positive effect sizes were found for arm-hand activities, self-reported amount of arm-hand use in daily life, and self-reported quality of arm-hand movement in daily life. Due to the size of the study sample and the low risk of bias, this result is classified as level 1 evidence, when referring to the original CIMIT treatment. Finally, a recent meta-analysis by Liu et al. (2017) also demonstrates that CIMIT and modified CIMIT might be more beneficial than conventional rehabilitation in the acute and subacute post-stroke phase.

Mirror therapy is a rehabilitation approach for stroke patients with upper extremity motor impairment (Veerbeek et al., 2014; Pollock et al., 2014; Brewer et al., 2013; Oujamaa et al., 2009) which is subtended by the hypothesis of the mirror neuron system, which discharges both on the occasion of performing a motor act or of simply observing it being performed by another subject (Hatem et al., 2016). This treatment consists of presenting visual feedback using a mirror placed in the midsagittal plane of the patient and reflecting the non-paretic side as if it was the affected one. Using this arrangement, the patient should be placed so that s/he sees only the reflection of the non-paretic upper limb in the mirror, creating for the patient the visual illusion of normal movements of the paretic limb (Pérez-Cruzado et al., 2017; Hatem et al., 2016).

Despite being a technique that emerged for the treatment of amputees' phantom limb pain and that has recently been used for patients after stroke, it has enough evidence to support its use in upper extremity recovery following stroke. Accordingly, the findings by Thieme et al. (2012) indicate evidence for the effectiveness of mirror therapy for improving upper extremity motor function, ADL and pain, at least as an adjunct to conventional rehabilitation for patients after stroke. Hatem et al. (2016) pointed out that there is moderate-quality evidence that mirror therapy is superior to sham therapy, control therapy or standard rehabilitation treatment with regards to upper extremity impairments and disabilities. Mirror therapy effects may persist till 6 months after treatment and it appears to be effective in the different phases of stroke. Pérez-Cruzado et al. (2017) confirmed that the combination of mirror therapy with conventional treatment showed greater effectiveness in the treatment of upper limb function in both acute and chronic stroke survivors. The authors added that for maximum effect, mirror therapy interventions should consist of 20-minute sessions delivered 5 days per week for 4 weeks. Finally, a recent meta-analysis by Zeng et al. (2018) also provided some evidence that mirror therapy may significantly improve motor function of the upper limb in patients with stroke, although the author insisted on the importance of carrying out studies to investigate this technique in more depth.

Mental practice with motor imagery is another emerging approach proposed for stroke patients (Veerbeek et al., 2014; Pollock et al., 2014; Oujamaa et al., 2009; Langhorne et al., 2009; Zimmermann-Schlatter et al., 2008). Mental imagery can be defined as the conscious representation of an action and is based on a subliminal activation of the motor neuron system. This approach is not only involved in performing a movement but also in imagining actions, recognizing various tools, comprehending another person's behaviour and observational learning (Oujamaa et al., 2009). The protocols used vary from one study to another, where the mental imagery exercises can be performed in the first (as an actor) and third person (as a spectator).

At present, mental practice with motor imagery seems to be valuable in improving upper extremity recovery in post-stroke patients. Different reviews and meta-analyses support its use. Hatem et al. (2016) showed moderate-quality evidence that mental practice in combination with another rehabilitation treatment is superior to the other rehabilitation treatment alone with regards to upper extremity impairments and disabilities and it appears to be effective in both the subacute and chronic phase. A Cochrane systematic review by Pollock et al. (2014) showed moderate-quality evidence indicating a beneficial effect of mental practice performed in addition to conventional exercise-based interventions on arm function and impairment. In contrast, Veerbeek et al. (2014) investigated mental practice combined with physical practice including RCTs with acute and chronic post-stroke patients, and they showed a significant positive effect size for arm-hand activities but non-significant effect sizes for motor function of the paretic arm, muscle strength, and basic ADL.

As to future lines of research, studies should be directed to a more specific cognitive assessment in order to differentiate the subjects capable of correctly performing mental imagery exercises from those who are unable to perform them correctly, and should also study in greater depth populations in the subacute post-stroke phase and with severe motor impairment (Oujamaa et al., 2009).

TECHNOLOGY SUPPORTED TRAINING

There has been a great advance in rehabilitation technology in the last decade that has created a large variety of new opportunities for patients and therapists (Timmermans et al., 2009). Robotics, virtual reality, and brain-machine interfaces, among others, are playing leading roles in this innovation process.

Virtual reality involves interactive simulations created by computer to provide a simulated practice environment, as well as feedback on movement execution or goal attainment (Pollock et al., 2014). Several virtual reality systems have been developed for motor rehabilitation of the upper extremity following stroke based on different paradigms and hypotheses such as learning by imitation, reinforced feedback, haptic feedback, augmented practice and repetition, action execution-observation, and others (Cameirão et al., 2008).

Currently, the most used virtual reality systems in rehabilitation processes are the IREX system, Rutgers Master II-ND and CyberGlove. Most trials conducted with virtual reality systems include a limited number of patients in the subacute or chronic post-stroke phase, with the presence of distal residual active movement and without previous cognitive deterioration and severe balance disorders (Bayón and Martínez, 2008).

Virtual reality training for the paretic arm resulted in a significant positive effect size for basic ADL, according to the result of the meta-analysis by Veerbeek et al. (2014). In contrast, a Cochrane review (Laver et al., 2011) investigating the use of virtual reality and interactive video gaming in stroke rehabilitation reported that there was limited evidence of any benefit in improving arm function and ADL when compared with the same dose of conventional therapy.

After analyzing the data, Hatem et al. (2016) showed that there is moderate-quality evidence that virtual reality is similar to standard intervention with regards to upper extremity impairment and disabilities and that this technique combined with another rehabilitation treatment is superior to the other rehabilitation treatment alone with regards to upper extremity impairment and activities. Concerning virtual reality immersion, there is moderate-quality evidence that it is superior to standard treatment with regards to upper extremity impairment and disabilities.

Virtual reality gaming has emerged with commercial gaming consoles in particular, being rapidly adopted in clinical settings (Laver et al., 2017). The literature supports the use of this rehabilitation therapy as equivalent to traditional therapies or as successful augmentation of those therapies (Yates et al., 2016). Hatem et al. (2016) showed moderate-quality evidence indicating its superiority to standard rehabilitation treatment with regards to upper extremity impairment.

Although individual trials have reported benefits, future studies should incorporate larger sample sizes and post-intervention follow-up (Yates et al., 2016), should demonstrate measures of efficacy for a particular type or degree of impairment (Dobkin et al., 2013) as well as developing new portable and low cost virtual reality systems that allow accessibility to this type of treatment even in the home setting (Bayón and Martínez, 2008). Regarding other more technical requirements, Oujamaa et al. (2009) also remarked that technological advances are expected to reduce the kinetosis linked to the time delay between the visual information received by the subjects and their movements performed in total immersion.

An up-to-date Cochrane review (Laver et al., 2017) found evidence that the use of virtual reality and interactive video gaming was not more beneficial than conventional therapy in improving upper limb function. Virtual reality may be beneficial in improving upper limb function and ADL function when it is used as an adjuvant to standard care. The authors also pointed out that time since onset of stroke, severity of impairment, and the type of device were not strong influencers of outcome. Furthermore, it was suggested that higher dose and customised virtual reality programmes were preferable.

Robotic-assisted treatment is another therapy that has been advocated to improve upper limb recovery (Veerbeek et al., 2014; Pollock et al., 2014; Brewer et al., 2013; Hayward et al., 2010). Robotic devices can move passive limbs, while providing assistance or resistance to movement of a single joint or control of intersegmental co-ordination (Mehrholtz et al., 2012). Currently, there are different systems named in the literature such as NeReBot, InMotion2 unimanual robot, Bi-Manu-Track robot, MIME robot, BATRAC, MIT-Manus robot, Myomo e100, and others (Oujamaa et al., 2009; Bayón and Martínez, 2008). The main advantages of using robot-assisted therapy are to deliver high-dosage, repetitive, interactive and high-intensity training (Veerbeek et al., 2014; Sivan et al., 2011; Bayón and Martínez, 2008). Most robotic devices are usually tailored for elbow and shoulder movements (Hatem et al., 2016). Such therapy can be used individually or combined with other therapeutic interventions such as the use of FES. The integrated use of FES and robotic devices is called

hybrid robotic rehabilitation and it has emerged as a promising approach for rehabilitation of upper limb motor functions (Resquín et al., 2016).

Meta-analyses by Veerbeek et al. (2014) resulted in significant positive effect sizes for motor function of the proximal part of the paretic arm, muscle strength, and pain with regard to shoulder-elbow robot-assisted therapy and in significant positive effect sizes for motor function of the paretic arm and muscle strength with regard to elbow-wrist robotics. A Cochrane review (Mehrholtz et al., 2012) reported that patients who receive electromechanical and robot-assisted arm training after stroke are more likely to improve their arm motor function and generic ADL. A recent systematic review with a meta-analysis of RCTs (Zhang et al., 2017) was carried out to evaluate the effectiveness of robotic training and conventional training in improving the motor recovery of paretic upper limbs in stroke patients. The authors concluded that this intervention appeared to have positive outcomes in enhancing motor recovery of the paretic upper extremity and they support robot-assisted therapy in addition to conventional treatment in order to help both therapists and patients in the management of upper limb recovery. In contrast, Hatem et al. (2016) observed that there was moderate-quality evidence that this therapy for the paretic upper limb is similar or inferior to standard treatment and, in addition, any gains obtained are specific to the task that is being practised and do not extrapolate to ADL. In the same way as the last-named author, Norouzi-Gheidari et al. (2012) demonstrated evidence of no benefit or harm of robotics, compared with the same duration of conventional rehabilitation.

Although there is evidence to suggest a potential future role for robotic-assisted therapy in stroke rehabilitation, the results must be interpreted with caution because there are variations between the trials in the duration and amount of training, type of treatment, and the patient characteristics (Mehrholtz et al., 2012) and moreover, there is much left to explore in this area (Brewer et al., 2013). Future large studies should determine the cost-benefit and clinical effectiveness of robotic therapies in stroke rehabilitation. It is still necessary to design robots that can re-educate more complex motor functions and establish therapeutic protocols that are cost-effective. As more studies are available that include a greater number of patients, with different degrees of motor impairment, further advances will be made in determining the efficacy and advantages of this therapy, which may contribute to the extension of its application in daily clinical practice (Bayón and Martínez, 2008).

Recent advances in neurotechnology have led to the development of *brain-computer interfaces* (BCIs) that translate brain activity into control signals of computers (Venkatakrishnan et al., 2014). These innovative technologies provide a means to decode mental states and activate devices according to user intentions, and could provide direct feedback on the engagement of motor areas of the brain surrounding the lesion site (Millán et al., 2010). BCI technology potentially promotes neuroplasticity and Hebbian-based motor recovery by rewarding cortical activity associated with sensory-motor rhythms through use with a variety of self-guided and assistive modalities (Remsik et al., 2016), yet a better understanding of mechanisms underlying brain recovery is required in order to improve efficacy of BCIs in stroke neurorehabilitation. As has already been mentioned, such intervention may be used individually, integrated with other therapeutic modalities or even combined with output devices such as FES (Silvoni et al., 2011). BCI with a FES system has been explored as a potential rehabilitation tool for motor learning after stroke because this combined system can assist such patients in learning and practicing the desired coordinated movements (Biasiucci et al., 2013; Müller-Putz et al., 2005).

Various studies have demonstrated clinical efficacy and support for use of BCI in stroke rehabilitation (Remsik et al., 2016; Soekedar et al., 2015; van Dokkum et al., 2015). To date, most studies have explored the benefits of the BCI rehabilitation approach in conjunction with conventional interventions, therefore significant evidence of superiority of BCI is still difficult to prove. Larger clinical studies are required with BCI-based neurorehabilitation interventions. There is room for potential use of BCI-based interventions on a smaller, more personalized scale as technology improves and allows for increased portability and compatibility. With increased accessibility to these therapies, a more diverse population will be able to benefit from this type of BCI treatment (Remsik et al., 2016).

CONCLUSION

Stroke is one of the leading causes of disability worldwide. Motor impairment due to stroke affects the patient's mobility, ability to perform daily activities and participation in society. All of these factors will impact greatly on the patient's quality of life. Rehabilitation of the arm following stroke is a complex intervention that integrates different modalities to treat deficits that are often multi-factorial and where different elements need to be considered, such as cognitive impairment, global motor function, patient outlook and adjustment to disability. Currently, approaches in treatments aimed at upper limb recovery are beginning to combine traditional methods with other complementary techniques described above in order to tailor treatment to the needs of the individual stroke patient.

Interdisciplinary collaboration is a key point in the treatment process. The availability of specific and up-to-date scientific evidence is crucial for professionals in order to make adequate evidence-based clinical decisions.

Implementation strategies should be put in practice in order to optimise the transfer of scientific knowledge into clinical practice. Several new techniques offer great promise for the future of stroke rehabilitation, although there are still many questions to be answered such as the clinical effect, the long-term outcomes, the cost-benefit of many of these interventions on functional recovery and the precise mechanisms of action of the various therapeutic strategies.

The methods and means available for the rehabilitation of these patients have varied hugely in recent years, with greater emphasis being placed on technological devices. It is still necessary to perfect and improve the design of these devices and to establish cost-effective treatment protocols in order to make them more accessible to daily clinical practice.

Scientific evidence related to stroke recovery will continue to grow in the coming years thanks to advances in neuroscience and neuro-imaging tests, as well as the increasing number of studies which are being undertaken on emerging new therapies that will contribute more data to neurorehabilitation and result in an improvement in the quality of life of these patients. In pursuit of this goal, an interdisciplinary effort combining various professionals from the fields of medicine, neuroscience and engineering is needed in order to achieve further progress.

BIOGRAPHICAL SKETCH

Name: Trinidad Sentandreu-Maño PhD

Affiliation: Department of Physiotherapy, University of Valencia, Valencia, Spain

Business Address:

Department of Physiotherapy
Faculty of Physiotherapy, University of Valencia
Gascó Oliag 5, 46010 Valencia (Spain)
trinidad.sentandreu@uv.es

Research and Professional Experience:

Assistant professor. Department of Physiotherapy, University of Valencia. Neurological physiotherapy.

Chapter 106

COGNITIVE IMPAIRMENT AND DEMENTIA FOLLOWING ISCHEMIC STROKE AND CARDIAC ARREST IN HUMANS

Mirosław Czuczwar*, MD, PhD

Second Department of Anesthesiology and Intensive Care,
Medical University of Lublin, Lublin, Poland

ABSTRACT

As the population is aging worldwide, the burden of cardiovascular diseases is constantly increasing. Ischemic heart disease and ischemic stroke are among the major causes of premature death and significant morbidity, resulting in already extremely high and increasing health care and social costs. One of the most challenging issues associated with the ischemic insult to the brain is the long-term cognitive impairment, observed in both stroke and cardiac arrest survivors. Recently, it has been shown that an ischemic brain event can be associated with the manifestation of a type of Alzheimer's disease neuropathology, possibly facilitating the development of dementia due to Alzheimer's disease. It also seems feasible to assess genetic predisposition and factors associated with an increased risk of developing Alzheimer's disease in the stroke survivors' population, similarly to cardiac arrest victims.

Future research efforts should focus on searching for pharmacologic and non-pharmacologic interventions to improve cognition, mental health, and quality of life of stroke and cardiac arrest survivors.

Keywords: Cardiac arrest, ischemic stroke, cognitive decline, dementia, Alzheimer's disease

INTRODUCTION

Both ischemic heart disease and stroke are increasingly prevalent in aging societies. Since they belong to the leading causes of death and disability worldwide, it is not surprising

* Corresponding Author's Email: czuczwarm@gmail.com.

that their economic burden is tremendous (Mozaffarian et al. 2016). There has been a significant improvement in the level of care delivered to the patients in the acute phase of the beforementioned diseases, resulting in significantly better survival rates. Unfortunately, the high prevalence of significant cognitive impairment observed in cardiac arrest and stroke survivors remains a challenge for both scientific and clinical communities. Numerous studies were published on the pathophysiology of the neuronal injury resulting from hypoxic-ischemic insult, and a lot of therapeutic approaches were investigated in both experimental and clinical settings (Thiel et al. 2014, Cronberg 2017). Unfortunately, in most cases, the primary goal was to increase the survival rates. Therefore, it should not be surprising that the results were either negative or inconclusive. It seems clear that future research should be focused on prevention of neurological damage and effective therapeutic approaches, which could improve neurological outcome after the brain insult. The primary objective of this chapter is to discuss the epidemiology of ischemic stroke and sudden cardiac arrest, as well as related mortality and morbidity, with a particular focus on the prevalence of dementia following the acute hypoxic-ischemic insult to the brain.

CARDIAC ARREST

Cardiovascular disorders are the most common cause of death worldwide (Mozaffarian et al. 2016). They contribute to approximately 75-80% of all cardiac arrests occurring in the pre-hospital setting, with the estimated global incidence of 62 per 100,000 person/years (Berdowski et al. 2010). In the United States, sudden cardiac arrest affects approximately 350,000 people each year, and mortality is attributed to 300,000 beings. Therefore, the above numbers give a meager survival rate of an estimated 8% (Nichol et al. 2008). The European survival rates after out-of-hospital sudden cardiac arrest are strikingly similar and remain as low as 10% on average, with the number of 275 000 people affected every year (Wissenberg et al. 2013). The high prevalence of premature deaths associated with the sudden cardiac arrest of cardiovascular origin has been the major contributor to launching new resuscitation guidelines. The broad implementation of the "chain of survival" concept, which includes bystander cardiopulmonary resuscitation, widespread access to automatic external defibrillators, and early coronary angiography with subsequent angioplasty, resulted in improved survival rates. National registries from Europe and USA show a 10% decline in mortality in the out-of-hospital cardiac arrest victims in the past two decades (Daya et al. 2015).

Nevertheless, despite many advances in the level of care delivered to the patients in both prehospital care and in-hospital management, the sudden cardiac arrest is still associated with high morbidity and mortality. There is a growing body of evidence that cognitive and functional impairment after cardiac arrest remains one of the significant areas of concern for physicians (Perez et al. 2016). The primary objective of the studies published in the past was to improve survival. In the real clinical setting, it seems more feasible to search for methods capable of enhancing the neurologic outcome, as the severity of hypoxic-ischemic brain injury is the primary determinant of survival. Therefore, it should not be surprising that research focus has shifted beyond prognostication in the acute period following successful cardiopulmonary resuscitation to the identification of mechanisms for long-term brain injury.

Another promising area of research is the implementation of therapies with a potential to reduce neuronal damage following hypoxic-ischemic brain injury.

The brain is extremely vulnerable to lack of constant supply of oxygen and glucose, due to its high metabolic rate and minimal energy supplies. When oxygen and glucose are not supplied in sufficient amounts to provide adequate ATP synthesis in the neurons, the patient loses consciousness, and the disappearance of electrical activity in the cerebral cortex on the electroencephalogram is observed within a few seconds. If blood flow is not promptly restored, exaggerating energy depletion will lead to anoxic depolarization with loss of membrane potentials, the release of excitatory glutamate, loss of ion gradients, and the influx of water and calcium ions, triggering further intracellular pathological processes. The beforementioned mechanisms explain how the sudden stop of cerebral blood flow, resulting from loss of pulse during a sudden cardiac arrest, leads to brain damage due to global cerebral ischemia (Busl and Greer 2010). It should be noted that the neurons in different parts of the brain vary regarding their vulnerability to ischemic-anoxic injury. The most profound damage is exerted to the hippocampus, cerebellum, and neocortex, while the brain stem neurons may remain intact for a significantly more extended period. The differential vulnerability to sudden cessation of blood flow explains why brain stem functions usually recover hours to days earlier than higher cortical functions. Therefore, the survivors of cardiac arrest in a minimally conscious or vegetative state may be successfully weaned from the mechanical ventilation and do not require prolonged circulatory support.

In patients successfully resuscitated from cardiac arrest, there is a broad spectrum of symptoms associated with neurological injury due to global brain ischemia and reperfusion. Since time from the collapse to return of spontaneous circulation is of the essence, the immediate assessment of neurological function may range from brain death to normal cognition, depending on factors such as the bystander cardiopulmonary resuscitation, the availability of automatic external defibrillator, and the identification of the potential reversible cause of the cardiac arrest (Lim et al. 2014). However, in most cases, patients who have been successfully resuscitated will be initially unconscious, apneic and display symptoms of hemodynamic instability, thus they will have to be admitted to the intensive care unit (ICU). In the initial period following the ICU admission, the leading cause of death is the circulatory/multiorgan failure, whereas during the later stages of hospital stay the poor prognosis is mainly determined by the magnitude of brain injury (Dragancea et al. 2013). Therefore, it should not be surprising that more than 50% of patients will not survive to hospital discharge. It has been recently advocated that to improve the patients' prognosis during the ICU stay the focus should shift from general circulatory, respiratory and metabolic optimization to evaluation of the extent and development of brain injury (Cronberg 2017).

The remaining survivors are not likely to be deemed fully recovered immediately after hospital discharge. They usually exhibit cognitive decline or impairment that reaches from mild to severe, including memory loss, decreases in psychomotor function, executive function, and visuospatial function. The beforementioned disturbances influence the vast majority of the affected population, with recent estimates as high as 88% (Andersson et al. 2015). It is beyond doubt that memory loss is the most commonly reported cognitive deficit among patients who regained consciousness following cardiac arrest. It is noteworthy that delayed recall and recognition memory are usually affected the most, while isolated memory loss is uncommon. It may be concluded that the usual pattern of impairment following cardiac arrest includes memory, subtle motor, as well as executive function deficits (Lim et al. 2004).

The assessment of neurological outcomes at hospital discharge is essential regarding immediate prognostication, but it seems increasingly important to improve the understanding of the full spectrum of cognitive and functional deficits observed in cardiac arrest survivors. According to recent studies, patients should undergo a careful assessment of deficits in long-term and short-term memory, cognitive impairment and possible progression to dementia, executive dysfunction, depression, decreased quality of life, and social participation (Perez et al. 2016). The prognosis for regaining cognitive functions to the pre-insult level is usually uncertain. The speed of cognitive rehabilitation usually reaches a plateau at the 3-month mark following resuscitation, yet lengthy rehabilitation has been shown to improve overall performance in a broad spectrum of activities and should be sought (Fertl et al. 2000). Many researchers have addressed the issue of prolonged disability due to cognitive deficits in cardiac arrest survivors at different time points. It seems evident that in the most cases patients are unable to resume their normal daily activities within the first year after the insult and the deficiencies specified earlier may be detectable for up to 8 years following the cardiac arrest (Lundgren-Nilsson et al. 2005, Mateen et al. 2011). A recent study from Sweden with an extremely long-term follow up of a mean of 17 years following a cardiac arrest showed a tendency towards lower scores on the cognitive testing and lower self-reported quality of life (Andersson et al. 2015). However, the authors found no evidence for an increased prevalence of depression, post-traumatic stress disorder or anxiety in the studied population. On the over hand, they concluded that cardiac arrest survivors might exhibit permanent cognitive impairments, including a progression to an Alzheimer's disease-type dementia (Andersson et al. 2015). The risk of dementia may be higher in the beforementioned population, because of the hypoxic event sustained during the collapse. A recent hypothesis links hypoxia to Alzheimer's disease-type molecular cortical abnormalities, perhaps facilitating the development of a dementia phenotype. It was demonstrated that transient hypoxia is associated with hyperphosphorylation of cytoskeletal proteins and abnormalities in neuronal mitochondrial function, which can lead to Alzheimer's disease-type lesions, as well as may elevate the level of amyloid β , a primary substrate in Alzheimer's disease pathology (Chen et al. 2003). Another possible pathway in Alzheimer's disease pathogenesis after ischemia is the dysregulation in the gene expression of amyloid protein precursor, β -secretase, presenilin 1 and 2 and tau protein, following global brain ischemia in the experimental model of cardiac arrest (Kocki et al. 2015, Pluta et al. 2016a, Pluta et al. 2016b, Pluta et al. 2018). Therefore, the cognitive decline following cardiac arrest is characterized by greater memory impairment than executive dysfunction, making it similar to prodromal Alzheimer's disease.

ISCHEMIC STROKE

A recent report on the global burden of stroke concerning incidence, prevalence, mortality, disability-adjusted life-years lost, and mortality-to-incidence ratios showed a growing burden of stroke globally and in low-income and middle-income countries in particular (Feigin et al. 2014). Another disturbing information is that although the mean age of patients with ischemic stroke is increasing in all countries, the proportion of patients younger than 65 years remains substantial, and more than 83 000 children and youths aged 20 years and younger are affected by stroke annually. The authors of the beforementioned report

have unquestionably demonstrated that despite encouraging data showing a significant decrease in mortality rates and mortality-to-incidence ratios, the absolute number of patients affected every year, stroke survivors, related deaths, and disability-adjusted life-years lost are vast and increasing over time. They also concluded that if these trends continue, by the year 2030 there will be almost 12 million stroke deaths, 70 million stroke survivors, and more than 200 million disability-adjusted life-years lost annually around the globe (Feigin et al. 2014). The data on increasing prevalence of stroke among patients aged 18-50 years old was recently confirmed by other authors, who estimated the incidence of stroke among young adults to be more than two million cases per year (Béjot et al. 2016). These cases are of extreme interest to the public health care and social systems, due to a considerable socioeconomic impact because of high health care costs and loss of labor productivity (Ekker et al. 2018). It should not be surprising that stroke-induced cognitive decline, which often progresses into dementia, is responsible for the substantial part of the costs associated with the healthcare and social services. The European data showed that the total annual cost of dementia, including post-stroke dementia, was about 105 billion euros in 2010 (Olesen et al. 2012). These costs will continue to rise in the future, because of the increasing prevalence of stroke and dementia in the aging population. Stroke and dementia often co-exist, and prevalence data show that at the time of the first stroke 10% of patients are already diagnosed with dementia, another 10% will develop dementia after the first stroke, and finally, 1/3 of patients will develop dementia following the stroke recurrence (Pendlebury and Rothwell 2009). Cognitive impairment following both ischemic and hemorrhagic stroke usually involves more than one cognitive domain. It is estimated that up to 65% of stroke survivors demonstrate multi-domain cognitive impairment that mainly contributes to increased caregiver burden and dependence in daily life activities and it may also significantly interfere with the potential benefits of physical rehabilitation and subsequent functional recovery (Donovan et al. 2008).

The data on the prevalence of post-stroke dementia are often elusive because they depend on the setting, the population, the exclusion criteria, the criteria used for the diagnosis of cognitive impairment, and the time interval since stroke (Henon et al. 2006). The lowest incidence (7%) is reported in patients after the first insult, while the highest one (41%) is associated with recurrent stroke and pre-stroke dementia. Interestingly, after the first episode of post-stroke dementia, the cumulative incidence increases linearly at a rate of 3% and 1.7% per year in hospital-based and population-based studies, respectively (Pendlebury and Rothwell 2009). In one of the few long-term studies on the incidence of post-stroke dementia, the cumulative incidence at year 25 was estimated at 48% (Kokmen et al. 1996).

The major problem in exploring the phenomenon of post-stroke dementia is that the borders between degenerative and vascular dementias often overlap, resulting in a mixture of pathologies in 20% of patients with cognitive impairment (Koistinaho and Koistinaho 2005). The pathophysiology of the cognitive decline in this challenging patient population may be a result of vascular, degenerative and inflammatory processes that may be present alone or in different combinations (Koistinaho and Koistinaho 2005). It was also reported that cerebral hypoperfusion, due to unilateral carotid stenosis, results in increased amyloid accumulation, which makes a clear association between stroke and Alzheimer's disease (Huang et al. 2012). The results of experimental studies have shown that the presence of amyloid augments the neuroinflammatory response after stroke (Whitehead et al. 2007). The abovementioned findings led to the formulation of a hypothesis for the development of post-stroke cognitive decline, which states that stroke triggers additional pathophysiological processes, capable of

initiating a secondary degenerative process, which subsequently may interact with pre-existing Alzheimer's disease pathology and thus accelerate neurodegeneration (Thiel et al. 2014). Therefore, it seems feasible to assess genetic predisposition and factors associated with an increased risk of developing Alzheimer's disease in the stroke survivors' population, similarly to cardiac arrest victims. It has to be kept in mind that in contrast to cognitive impairment caused by Alzheimer's disease, vascular cognitive impairment is associated with vascular factors and does not mainly affect memory but many different cognitive domains. However, some domains such as executive functions or speed of mental processing are more likely to be affected (Brainin et al. 2015).

CONCLUSION

The prevalence of ischemic heart disease and ischemic stroke and their burden for health care and social systems worldwide is increasing due to many different factors. This phenomenon is partly because of hypoxic-ischemic brain injury, resulting from the abovementioned diseases, almost inevitably leads to global neurological dysfunction and persistent cognitive decline. Future research efforts should focus on searching for pharmacologic and non-pharmacologic interventions to improve cognition, mental health, and quality of life of stroke and cardiac arrest survivors.

ABSTRACT

In this chapter, we compared motor and non-motor symptoms between experimental brain ischemia and ischemic stroke in patients, and noted that ischemia-reperfusion injuries influenced cognition and dementia development. Ischemic stroke in humans is a leading cause of disability. Dementia after ischemic stroke affects up to one third of stroke survivors. Investigations and therapeutic actions have historically focused mainly on physical disabilities, when cognitive deterioration, an important symptom for post-stroke survivors, has been quite neglected. Even a minor stroke affects daily functioning, executive functions, and cognition, consequently affecting participation, the quality of life, and return to work. Stroke survivors are at an increased risk of developing cognitive impairment. Obviously, the acute tissue damage may affect cognition. Nevertheless, despite prospective data being available, the results are conflicting and the direct

* Corresponding Author's Email: pluta@imdik.pan.pl.

cognitive effect of a stroke event beyond the cognitive decline associated with age and vascular risk factors remains poorly understood. Physical impairments following ischemic stroke tend to improve to a greater or lesser degree. However, for reasons which remain unknown, cognitive impairments progressively worsen. One year after experimental brain ischemia rats showed: hearing dysfunction, hyperactivity, problems with adaptation to a new environment, reduced anxiety, learning and memory impairment in a battery of hippocampal dependent tests. Post-stroke dementia in humans is associated with factors indicating a reduced cognitive reserve (low education, white matter lesions, and brain atrophy) and is also strongly associated with stroke factors (damage size, multiple lesions and stroke recurrences) indicating the likely impact of optimal acute stroke care and secondary prevention in reducing the burden of dementia.

Keywords: dementia, stroke, transient ischemic attack, brain ischemia, cognition, behavior, personality, brain atrophy, human, experimental study

INTRODUCTION

Dementia is a common term for symptoms presented by patients with different kinds of cognitive disability. These symptoms include impaired mental activities in such areas as: learning, memory, attention, judgment, concentration, thinking and language. They are often accompanied by changes in personality and behavior. It is a debilitating neurodegenerative syndrome which causes a gradual and irreversible decline in cognitive, physical and social function (Landeiro et al., 2018). Dementia is a condition with little prospect of a cure or preventing its progression (Landeiro et al., 2018) and is caused by more than 60 different disorders. It appears mostly in people over 65 years of age, and an increase in figures and costs is associated with greater longevity as a result of reduction in the number of people dying prematurely. In 2014, it was estimated for circa 7% of people aged 65 and above worldwide (Landeiro et al., 2018). There are different types of dementia and some patients may have a combination of types. Alzheimer's disease type dementia is the most common and accounts for more than 60-80% of diagnosed dementias (Landeiro et al., 2018). Next common form of dementia is vascular dementia, usually as a succession, connected with different ischemic brain lesions. Dementia also has an effect on social and economic costs. It is forecast that the dementia will advance exponentially in the coming decades, when the older part of the population will continue to grow in age. The challenge facing Europe and the world lies in developing an interdisciplinary combination of clinical, medical, economic, governmental, social and personal approaches to those with dementia and their families. Dementia does harm not only to patients but to caretakers, families, communities and national healthcare systems.

In 2010, circa 17 million cases of ischemic stroke have been reported worldwide and the number of patients living after an ischemic stroke accounted for 33 million (Brainin et al., 2015, Bejot et al., 2016). The annual cost of dementia, turning to post-stroke dementia, was calculated to be 105 billion dollars in Europe in the above year (Brainin et al., 2015). Today, dementia affects circa 50 million people worldwide, with this number expected to increase to 75 million by 2030 and to 132 million by 2050 (Frankish, Horton 2017, Livingston et al., 2017), which is driven to a large extent by population ageing. Dementia as a syndrome of brain damage causes not only disability and dependency for individuals affected by the

disease, but it can also have a strong detrimental effect on handlers, especially on family caretakers, who are at a high risk of developing anxiety disorders and depression (Frankish, Horton 2017). Currently the cost of caring for patients with dementia is more than 800 billion dollars per year worldwide (Livingston et al., 2017), increasing to 2 trillion dollars by 2030 (Frankish, Horton 2017). Its high prevalence, progression and enormous requirements for care and social support lead to a public health crisis. Dementia is a huge worldwide challenge for healthcare system and social care in the 21st century.

Society is aging, the population lives longer and dementia is growing rapidly. The incidence of dementia is difficult to determine finally because many cases remain undiagnosed. Dementia is not caused by aging, nor is it an integral part of the aging processes. It is more likely a combination of environmental, genetic and age-associated processes. Despite the huge resources currently directed at biomedical research of neurodegenerative diseases such as Alzheimer's disease and brain ischemia, no etiology and cure is in sight. Only some symptomatic and palliative therapies are available, although the knowledge of neurological processes, especially among the elderly population, is increasing rapidly. Actually, the dominant trend is to shift responsibilities from national support policies to the families which are not prepared for that. Currently, dementia is a growing wave and a neglected problem at the same time. Today our goal is to promote efforts to find communal solutions and interventions that preserve people's humanity and delay institutional care.

Ischemic brain injury has been recognized as a trigger of Alzheimer's disease (Pluta et al., 1994, Pluta 1997, Honig et al., 2003, Pluta 2006, Pluta, Ułamek 2006, Pluta 2007a, Pluta 2007b, Pluta, Ułamek 2008, Pluta et al., 2009, Pluta et al., 2010a, Pluta et al., 2010b, Pluta et al., 2013a, Pluta et al., 2013b, Kocki et al., 2015, Pluta et al., 2016a, Pluta et al., 2016b, Ułamek-Kozioł et al., 2016a, Ułamek-Kozioł et al., 2016b, Pluta et al., 2017, Salminen et al., 2017, Ułamek-Kozioł et al., 2017, Pluta et al., 2018). Patients with Alzheimer's disease, who have ischemic lesions, were found to have more intense dementia (Snowdon et al., 1997). Shared susceptibility to Alzheimer's disease and ischemic brain lesions might explain the frequent association of both disorders. In this chapter, we used data from different laboratories and clinics to compare the relationship between dementia after ischemic brain injury with dementia associated with Alzheimer's disease. If the history of stroke proceeds the development of dementia such a relationship cannot be excluded. It was noted that the history of ischemic stroke was associated with the subsequent development of Alzheimer's disease, primarily in the presence of other risk factors related to both cardiovascular and ischemic brain injuries. On the other hand, it is possible that Alzheimer's disease might increase the likelihood of ischemic stroke. The presence of neuropathological changes in Alzheimer's disease brain could predispose some patients to ischemic stroke, perhaps owing to amyloid angiopathy, brain tissue changes, or the secondary consequences of the β -amyloid peptide neurotoxicity. It needs to be established whether ischemic stroke is directly involved in the neuropathogenesis of Alzheimer's disease or acts indirectly as a contributor to the manifested symptoms of Alzheimer's disease. Nonetheless, prevention and/or treatment of ischemic stroke may have important implications for Alzheimer's disease risk and deserve further investigation. For example, pre-existing brain damage by ischemic stroke might additionally increase the likelihood of Alzheimer's disease by increasing the extent of injury from the genomic and proteomic cascade of Alzheimer's disease.

DEMENTIA FOLLOWING ISCHEMIC STROKE IN HUMANS

During three months observations of patients after ischemic stroke it was noted that 57.2% of survivors had a mild disability, 9.4% - moderate disability and 18.6% - severe disability (Surawan et al., 2017). As presented above, ischemic brain injuries in humans are the most common progressive causes of disability worldwide and eventually have a negative impact on the patients, caregivers and society as a whole (Flynn et al., 2008). Brain ischemia patients suffer from progressive neurological deficits that significantly limit their ability to return completely to society (Surawan et al., 2017). An insidious consistency of post-ischemic brain alterations is a slow and progressive development of post-ischemic dementia (Desmond et al., 2002, Jellinger 2007, Pinkston et al., 2009, Zhang et al., 2010, Gemmell et al., 2012, Brainin et al., 2015, Mok et al., 2016, Portegies et al., 2016, Kim, Lee 2018) which is associated with severe neurological disability (Surawan et al., 2017). Dementia is the worst consequence for patients after ischemic brain injury and it is responsible for approximately 20% of all diagnosed dementias (Fillit, Hill 2002). Worldwide, dementia, after ischemic stroke, varies from 5% to 50% depending on the diagnostic criteria, population demography and geographic location (Leys et al., 2002, Zhang et al., 2010, Surawan et al., 2017). In fact, now it is clear that dementia following brain ischemia-reperfusion incidence has many risk factors in common with late development of sporadic Alzheimer's disease. There is a high probability that brain ischemia lesions may precede the onset of Alzheimer's disease type dementia and trigger all the consequences associated with the development of dementia. Dementia following ischemia associated with progressive delayed secondary alterations occurs in the people suffering from transient ischemic attack, lacunar, focal and salient ischemic brain episodes in a progressive manner (Bornstein et al., 1996, Jellinger 2007, Pinkston et al., 2009, Gemmell et al., 2012, Mok et al., 2016, Bivard et al., 2018). The chronic post-ischemic injuries have received far less attention in experimental and clinical dementia investigations. Epidemiological studies have presented that the prevalence of dementia in survivors after brain ischemia is about 9 times higher than in controls without stroke after 3 months (Tatemichi et al., 1992, Pohjasvaara et al., 1998, Madureira et al., 2001, Surawan et al., 2017), and after a lacunar infarct 4–12-fold higher than in healthy people after 4 years (Loeb et al., 1992). In long term-based observations of survivors after ischemic stroke it was demonstrated that the incidence of dementia amounted to 7% after 1 year (Tatemichi et al., 1990). It was reported that 32% of survivors, who were at the beginning free of dementia, developed it over 5 years after the first ischemic incidence (Bornstein et al., 1996). Another study has shown that the combined proportion of survivors with dementia constituted 21% during 3 years of observation (Henon et al., 2001). The examined survivors after brain ischemia develop dementia in around 22% by the end of 4 years in the follow-up time (Altieri et al., 2004). In the studies of patients at different times after ischemic stroke it was documented that the incidence rate of dementia achieved 7% in 1 year, 10% in 3 years, 15% in 5 years and 23% in 10 years of observation (Kokmen et al., 1996). In two different studies of survivors after a lacunar brain ischemia episode, it was found that 5-10% of cases had dementia after 1-3 years of observation (Samuelsson et al., 1996), and in the other report that 23% of survivors developed dementia during 4 years of survival (Loeb et al., 1992). Still, the incidence of dementia following recurrent ischemic stroke was 33.33% (Surawan et al., 2017). Global ischemia in childhood frequently leads to poor neurologic outcomes, including

memory and learning deficits (Dietz et al., 2018). In the novel model of childhood transient global brain ischemia memory is impaired during seven days after ischemia and completely recovers through 30 days (Dietz et al., 2018).

DEMENTIA FOLLOWING EXPERIMENTAL ISCHEMIC BRAIN INJURY

In addition to neuronal injuries caused by ischemia and recirculation, behavioral alterations have been observed, too (Block 1999, Barra de la Tremblaye, Plamondon 2011, Kiryk et al., 2011, Li et al., 2011, Pluta et al., 2011, Cohan et al., 2015). Injury after ischemia and recirculation does not result in long-lasting neurological deficits in experimental animals (Block 1999). Spontaneous restoration of sensorimotor activities has been observed in the period following ischemia (Popa-Wagner 2007, Yang, Simpkins 2007, Kiryk et al., 2011). After ischemia-reperfusion brain alterations in animals, locomotor hyperactivity has been noted (Kuroiwa et al., 1991, Karasawa et al., 1994) such as in Alzheimer's disease patients. The hyperactivity was related to the death of pyramidal neurons in hippocampus (Kuroiwa et al., 1991). A longer time of ischemia and, consequently, a longer duration time of locomotor hyperactivity is directly correlated with a raised number of neuron loss in hippocampus and neuroinflammation (Block 1999, Langdon et al., 2008, Pluta et al., 2010a, Sekeljic et al., 2012). After ischemia-reperfusion brain injury, impaired habits, as manifested through an increase in examination time, were shown (Milesen, Schwartz 1991, Colbourne, Corbett 1995). Brain ischemia causes reference and working memory deficiency (Davis et al., 1986, Kiyota et al., 1991, Kiryk et al., 2011). Ischemia-reperfusion brain injury in experimental animals leads slowly to spatial memory deficits over the recirculation period (Block, Schwarz 1998, Karhunen et al., 2003, Kiryk et al., 2011). Progression of cognitive deficits has been observed every time during recirculation phase (Roof et al., 2001, Karhunen et al., 2003, Kiryk et al., 2011). In addition to that, observations of repetitive transient brain ischemia injury in animals have shown durable locomotor hyperactivity, persistent cognitive deficits and decreased anxiety (Ishibashi et al., 2006). The behavioral abnormalities, mentioned above, were related to an enormous brain atrophy (Hossmann et al., 1987, Pluta 2000, Pluta 2002, Pluta et al., 2009, Jabłoński et al., 2011, Pluta et al., 2012a, Pluta et al., 2012b), neuron loss in the CA1 area of hippocampus, caudate nucleus, brain cortex (Ishibashi et al., 2006, Pluta et al., 2009, Pluta et al., 2010a, Pluta et al., 2012b), amygdala and perirhinal cortex (Barra de la Tremblaye, Plamondon 2011). Alertness and sensorimotor capacities are affected within 1–2 days whereas the deficits in learning and memory appear to be slowly irreversibly progressing and lasting for good (Langdon et al., 2008, Kiryk et al., 2011).

CONCLUSION

Removal and prevention of the dementia and neurological consequences after brain ischemia is an issue that scientists and neurologists spend only little time on. In some survivors, a spontaneous neurological restoration is shown within weeks and/or months after an ischemic episode. Notwithstanding, in general, a spontaneous restoration and/or recovery is partial. Furthermore, brain ischemia episode frequently results in a complete functional

devastation of its victims and, as a consequence, is the leading cause of permanent disability of survivors who require permanent institutional care. The loss of quality of life over the years and financial resources spent on healthcare are staggering. The circumstance is even deteriorated by the fact that no causal treatment is available for the cases during and after acute ischemic brain injury. The social burden after brain ischemia increases dramatically. Thus, the knowledge of the underlying progressive neuropathological mechanisms is urgently required. This chapter tends to collect together the pathological alterations during recirculation period and reveals convincing molecular mechanisms. To summarize, the basis of evidence from both experimental and clinical studies revealed that the slow progressive impairment of cognitive functions could not be explained only by the direct influence of the ischemic brain injury, but rather by a progressive effect of the additive factors after ischemic injury, e.g., Alzheimer's disease related factors, and finally, aging (Pluta et al., 1994, Wiśniewski et al., 1995, Pluta 1997, Honig et al., 2003, Pluta 2006, Pluta, Ułamek 2006, Jellinger 2007, Pluta 2007a, Pluta 2007b, Popa-Wager 2007, Langdon et al., 2008, Pluta, Ułamek 2008, Pluta et al., 2010b, Pluta et al., 2011, Gemmell et al., 2012, Pluta et al., 2012a, Pluta et al., 2012b, Pluta et al., 2013a, Pluta et al., 2013b, Kocki et al., 2015, Pluta et al., 2016a, Pluta et al., 2016b, Portegies et al., 2016, Ułamek-Kozioł et al., 2016a, Ułamek-Kozioł et al., 2016b, Ułamek-Kozioł et al., 2016c, Pluta et al., 2017, Salminen et al., 2017, Ułamek-Kozioł et al., 2017, Pluta et al., 2018). The above suggestions have been confirmed by ischemic overexpression of amyloid protein precursor and its amyloidogenic processing secretases' genes, which may be strongly involved in the deterioration of cognitive activities in the recirculation period (Shi et al., 1998, Shi et al., 2000, Pluta et al., 2013a, Pluta et al., 2013b, Kocki et al., 2015, Pluta et al., 2016a, Pluta et al., 2016b). The production of β -amyloid peptide after brain ischemia increases and influences negatively the memory (Yan et al., 2007). Additionally, a pathological expression of tau protein gene after ischemia (Pluta et al., 2018) and deposition of α -synuclein might disturb the synaptic function, resulting in cognitive deficits (Hashimoto, Masliah 1999). The functional changes precede the neuronal cell final degeneration within the sectors of selective vulnerability to ischemic episodes. Furthermore, regions of brain, that do not have ischemic neuronal cell injury, demonstrate functional abnormalities. The above abnormalities seem to be mostly caused by synaptic insufficiency in communication of neurons between ischemic sectors with damaged or dead neurons.

During the last 25 years, a growing body of evidence has implied a close relationship between brain ischemia episodes and Alzheimer's disease. Different investigations, including clinical epidemiological studies, have paid attention to a relationship between neurovascular risk factors and Alzheimer's disease development. The link between Alzheimer's disease and cerebrovascular diseases has been supported by the following facts: (1) Alzheimer's disease may increase the likelihood of suffering from ischemic stroke and vice versa (Pluta 2004a, Pluta 2004b), (2) the deposition of the β -amyloid peptide in the brain tissue of Alzheimer's disease patients toxically affects neurons (Hardy, Selkoe 2002) and vascular system (Paris et al. 2004a, Paris et al., 2004b), and what is even more, (3) Alzheimer's disease and atherosclerosis share environmental and genetic risk factors like apolipoprotein E e4 polymorphism, hypertension, hypercholesterolemia, metabolic syndrome and obesity (Casserly, Topol 2004).

Data from this chapter demonstrate a relationship between the history of ischemic stroke and Alzheimer's disease development. Thus, there was an increased risk of Alzheimer's

disease development with the severity of dementia symptoms (Snowdon et al., 1997) in persons with the history of ischemic stroke. The risk was the highest for those patients with ischemic stroke who also had established vascular risk factors, such as heart disease, high blood pressure or type 2 diabetes mellitus. The relationship of Alzheimer's disease risk factors with stroke remained the same. The worldwide problem and enormous costs involved make it clear that there is an urgent need for advances in the prevention and/or treatment of brain ischemia-reperfusion injury and its irreversible consequences like post-ischemic dementia. The growing problem of dementia which occurs following ischemic stroke forces an increase of funding resources for clinical and basic research. Recently, no established methods of prevention and no cure have been available once the dementia becomes manifested. Significant cortical, hippocampal and medial temporal lobe atrophy with white matter changes are observed in the development of cognitive decline after ischemic stroke (Hossmann et al., 1987, Pluta 2000, Pluta et al., 2008, Pluta et al., 2009, Bivard et al., 2018). The dynamics of the above ischemic changes and their further progress are being strongly studied at present. Future studies are required to clarify the interaction between degenerative, vascular, and systemic processes in the development of stroke-associated dementia. Genetics related to Alzheimer's disease and factors associated with an increased risk of developing Alzheimer's disease also need to be investigated.

STROKE AND ALZHEIMER'S DISEASE: COMMON MECHANISMS AND THERAPEUTIC APPROACHES

Lidija Radenovic*, PhD and Pavle R. Andjus, PhD

Center for Laser Microscopy, Faculty of Biology,
University of Belgrade, Belgrade, Serbia

ABSTRACT

Stroke and Alzheimer's disease (AD) have been placed in different areas of neurology. They are considered to be examples of different forms of brain dysfunction - stroke, as an acute cerebrovascular injury, and dementia as a progressive, chronic neurodegenerative disease. However, there are overlaps in pathophysiological mechanisms between these brain conditions. Moreover, stroke increases the likelihood of developing AD, by initiating degenerative dementia. There is evidence that stroke risk factors such as age, hereditary factors, hypertension, diabetes mellitus, lipid disorders, obesity, atrial fibrillation, ischemic heart disease, tobacco smoking, and physical inactivity, are independently associated with an increased risk of AD, up to fivefold in the elderly.

Stroke leads to increased extracellular levels of glutamate causing excitotoxicity, peri-infarct depolarisations, inflammation, mitochondrial dysfunction, oxidative/nitrosative stress, and apoptosis. On the other hand, AD is characterized by progressive cognitive deficits, accumulation of amyloid- β and intracellular neurofibrillary tangles, and neuronal death. Increasing evidence suggest that amyloid-independent factors such as stroke-related, also contribute to AD pathogenesis. There are many similarities in different molecular mechanisms of neuronal cell death observed in stroke and AD.

The possible therapeutic targets should be in connection with the common underlying pathophysiological mechanisms in stroke and AD, such as excitotoxicity, oxidative stress, neuroinflammation, and apoptosis. Moreover, new and creative approaches are needed for the stimulation of endogenous neurogenesis and synaptogenesis, as well as for exogenous neuroreplacement.

INTRODUCTION

Stroke and Alzheimer's disease (AD) have been placed in different areas of neurology. They are considered to be examples of different forms of brain dysfunction - stroke, as an acute cerebrovascular injury, and dementia as a progressive, chronic neurodegenerative disease. However, there are overlaps in pathophysiological mechanisms between these brain conditions. Moreover, stroke increases the likelihood of developing AD, by initiating degenerative dementia (Pluta et al., 2009). Dementia in elderly stroke survivors is associated with medial temporal lobe atrophy (Saito et al., 2014). Hippocampal neuronal atrophy is apparent for dementia in both cerebrovascular and neurodegenerative diseases (Gemmell et al., 2012; Kocki et al., 2015). Given the high prevalence of AD, identifying prognostic markers in stroke patients would be a substantial step forward (Cumming and Brodtmann, 2011).

Stroke is the leading cause of mortality and morbidity worldwide. It is also a leading cause of disability, with a high prevalence of new or recurrent stroke events (Lakhan et al., 2009). Yet, the only drug of the US Food and Drug Administration approved for pharmacological treatment of stroke is tissue plasminogen activator, which due to the limited therapeutic post-stroke time window (≤ 4.5 h) is only administered to 2–5% of patients. Administration beyond this period has accompanying complications, such as the hemorrhagic transformation (Brainin et al., 2007; Sehba et al., 2013). So, it is necessary to continue searching for novel therapeutics.

Stroke is, also, an important cause of cognitive deficits. The term cerebrovascular dementia is used to describe dementia attributed to stroke, or deep white matter lesions detected with imaging methods (Sahathevan et al., 2012). The relationship between AD and cerebrovascular dementia is unclear, although significant overlaps exist. There is evidence that the stroke risk factors such as age, hereditary factors, hypertension, diabetes mellitus, lipid disorders, obesity, atrial fibrillation, ischemic heart disease, tobacco smoking, and physical inactivity, are independently associated with an increased risk of AD, up to fivefold in the elderly (Kalogeris et al., 2012; Ulamek-Kozioł, et al., 2016a). Evidence suggests that these risk factors have a cumulative effect on AD development, but not on cerebrovascular dementia (Sahathevan et al., 2012; Ulamek-Kozioł, et al., 2016c).

The primary consequence of stroke in patients, animal models, as well as *in vitro* models is a reduction in energy substrates, including glucose and oxygen (Dirnagl et al., 1999; Lipton, 1999; Korenic et al., 2015). In addition, ATP synthesis through glycolysis and oxidative phosphorylation is dysregulated, with a rapid decline in cellular ATP levels. Stroke leads to increased extracellular levels of glutamate causing excitotoxicity, peri-infarct depolarisations, inflammation, mitochondrial dysfunction, oxidative/nitrosative stress, and apoptosis (Kagaya et al., 2016).

AD is a neurodegenerative disease with clinical hallmarks of memory loss, dementia, and cognitive deficits. It is a chronic disease with well-defined pathophysiological mechanisms, mostly affecting medial temporal lobe and associative neocortical structures (Skaper, 2012; Pluta et al., 2016). Neuronal injury can be observed in the basal forebrain, frontal lobe, hippocampus and cerebral cortex of both patients and animal models (De-Paula et al., 2012; Ulamek-Kozioł, et al., 2016b). AD is characterized by progressive cognitive deficits, accumulation of amyloid- β (A β) and intracellular neurofibrillary tangles, and neuronal death. According to the amyloid hypothesis of AD, the overproduction of A β is a consequence of the disruption of processes that regulate the proteolytic cleavage of the amyloid protein precursor (APP). Genetic, age-related and environmental factors contribute to a metabolic shift favoring the amyloidogenic processing of APP (De-Paula et al., 2012; Pluta et al., 2013a). The resulting protein aggregates are causing synaptic dysfunction, characterized by dendritic spine loss and reduced post-synaptic density, leading to disturbance of network connections and cell death (Duncan and Valenzuela, 2017). The cognitive deficit is a consequence of neural network activity caused by dendrite retraction, dendritic spine and synaptic degeneration, and the death of cholinergic neurons in the basal forebrain and the entorhinal cortex (Huang and Mucke, 2012). Additionally, mitochondrial dysfunction and free radical damage are also hallmarks of AD brain (Hayashi et al., 2006).

The AD pathology is diverse and of multifactorial origin (Pluta et al., 2004a; 2009; 2012; 2013b). Thus, tau protein, an intracellular microtubule-associated structural and transport protein, becomes hyperphosphorylated, leading to microtubule collapse and aggregation into neurofibrillary tangles. On the other hand, cleavage of the APP by secretases leads to the formation of amyloid plaques as extracellular aggregates of A β fragments. The plaques and neurofibrillary tangles are related to the accumulation of the A β peptide in brain, and to cytoskeletal changes. A particular feature of AD is the association of activated microglia and resident macrophages with plaques. Present in the early stages of the disease, their number in AD brains declines with disease advancement. Activated microglia produce humoral immune factors – cytokines, which modulate neuroinflammation. Extensive neuronal and synaptic loss represents the end stage of AD (Duncan and Valenzuela, 2017).

It is clear that different cellular mechanisms can lead to AD, yet no definitive therapy exists. Current therapy is limited to the potentiation of cholinergic transmission in the nucleus basalis to compensate presynaptic cholinergic deficiency, and the prevention of N-methyl-D-aspartate (NMDA) receptor activity during cognitive loss. However, present therapies are limited and may provide only symptomatic relief (Chonga et al., 2005). The pharmacological treatment of AD currently relies on inhibition of acetylcholinesterase (Shah and Reichman, 2006). This inhibition increases the concentration of acetylcholine at cholinergic synapses to promote neurotransmission. In addition, ongoing clinical trials aim to reduce synapse degeneration by targeting APP processing mechanisms, A β production and aggregation (Huang and Mucke, 2012). Although these treatments may improve cognitive function by reducing disease progression, regeneration of damaged neurons is still without pharmacological treatment (Smith et al., 2017).

ANIMAL MODELS OF STROKE AND ALZHEIMER'S DISEASE

With an increasingly aging population, high incidence of stroke, and limited therapies, it is important to improve functional recovery of stroke survivors (Livingston-Thomas and Tasker, 2013). Animal models are very important for understanding the mechanisms underlying neuroprotection and rehabilitation. Neuroprotective drugs are effective in experimental stroke studies, but none have proven clinically effective. A number of reasons have been discussed, such as unpredictable models, weaknesses in the design of experimental studies, as well as problems in achieving effective drug concentrations without severe side effects (Schaar et al., 2010).

Since stroke is a very diverse condition there is no ideal experimental model. Criteria to consider include pathophysiological processes, lesion size, and reproducibility (Livingston-Thomas and Tasker, 2013). While animal models remain crucial to basic stroke research, there are limitations in the translation to clinical practice. Stroke models represent a simplified version of very complex human condition. Gender, age, pre-stroke condition, stroke severity and co-morbidities are highly variable in the clinical population, but controlled in experimental studies (Livingston-Thomas and Tasker, 2013). However, rodents still serve as preferred models for understanding the effects of human stroke (Livingston-Thomas and Tasker, 2013).

AD is an increasing burden for patients and society, as more people live long enough to become affected (Bates et al., 2014). However, there is still the lack of an animal model that accurately replicates AD. Furthermore, as age remains the strongest risk factor for AD, transgenic models in which mutant human genes are expressed throughout the life of the animal provide only limited insight into age-related factors in disease development. Guinea pigs (*Cavia porcellus*) are of interest in AD research, because they have a similar A β sequence to humans and thus, with aging may present a useful non-transgenic animal AD model (Bates et al., 2014). Transgenic mice overexpressing human APP have been used to model A β pathology (Dewachter et al., 2000; Maia et al., 2013), as well as the rabbit model (Bitel et al., 2012). In addition, various higher vertebrate models have been in use to study the pathophysiology of AD, but these models have limitations regarding ethical restrictions, high cost, difficult maintenance and lesser reproducibility. On the other hand, various lower chordate animals such as *Danio rerio*, *Drosophila melanogaster*, *Caenorhabditis elegans* and *Ciona intestinalis* have proven to be important *in vivo* models for the determination of drug targets (Sharma et al., 2017).

Despite the genetic and cellular evidence that supports the amyloid hypothesis, it is becoming increasingly clear that AD etiology is complex and that A β alone is unable to account for all aspects of AD. There is increasing evidence to suggest that stroke also contributes to AD pathogenesis (Skaper, 2012).

THE CONNECTION BETWEEN PATHOPHYSIOLOGY MECHANISMS AND THERAPEUTIC APPROACHES IN STROKE AND ALZHEIMER'S DISEASE

As already pointed out, AD and cerebrovascular dementia are the major causes of cognitive deficits worldwide. Considerable evidence indicates that cerebrovascular

dysfunction and stroke are associated with neurodegenerative processes in aged population, preceding cognitive decline and dementia. Although AD is considered as the most common cause of dementia, AD patients commonly also exhibit cerebrovascular dysfunctions (Sahathevan et al., 2012). AD and cerebrovascular disorders, including stroke, are the leading causes of dementia in the elderly (Pluta et al., 2004b). The progression of neuropathological changes in AD patients initiates years to decades, before the diagnosis of dementia. Therefore, a considerable effort has been made to identify factors that contribute to the pathogenesis of AD. Among these factors are cerebrovascular disorders, stroke, and microvascular alterations affecting the progression of dementia. Cerebrovascular dysfunction has emerged as an early event in AD, including changes in all cell types of the neurovascular unit - astrocytes, pericytes, vascular smooth muscle cells and endothelial cells (Pimentel-Coelho and Rivest, 2012; Pluta et al., 2012).

In addition, persistent systemic hypoxia, a direct consequence of cerebrovascular dysfunction, can compromise the brain by increasing the risk of developing AD. Clinical evidence confirms that structural and functional changes characteristic of AD pathology also occur following stroke (Cumming and Brodtmann, 2011). Moreover, cerebrovascular dysfunction promotes tau protein phosphorylation, modulates apolipoprotein E expression, and has more profound effects in aged animals (Villarreal et al., 2014). In addition, it was found in the ischemia-reperfusion long-lived rats (9 and 13 months after 10 min of cardiac arrest), blood-brain barrier leakage in the area of the dorsal hippocampus and brainstem-hindbrain level in basal cerebellum, as well as inflammatory processes backed by microglial activity, even up to 1 year after ischemia-reperfusion (Sekeljic et al., 2012). Studies with transgenic and non-transgenic mouse models show that hypoxia increases the levels of A β peptides in the brain. Thus, stroke can trigger accelerated amyloid deposition, through interference with amyloid clearance pathways (Pluta et al., 2017). Consequently, there are therapeutic approaches targeting the cerebrovascular system for preventing AD (Pimentel-Coelho and Rivest, 2012).

Longitudinal clinical studies suggest the co-morbidity of stroke and AD (Kalaria, 2000). In addition, more than 30% of stroke survivors will develop dementia within two years (Kalaria, 2012). Stroke and neurodegenerative diseases are additive and accelerate dementia. Medial temporal lobe atrophy is a predictor of dementia. It appears as a feature in demented stroke survivors with minimal AD pathology. The atrophy is attributed to smaller cell volumes in the hippocampus and frontal lobe that reflect loss of neuronal connectivity. Therapeutic strategies that restore functional morphology in surviving neurons could prevent further cognitive decline in stroke and AD (Kalaria, 2012).

The concept of mixed dementia has been confirmed in patients with brain condition showing both AD and cerebrovascular disorder, i.e., cerebrovascular dysfunction along with A β -associated neurotoxicity, and tau protein - hyperphosphorylation. In addition, the important role of neurovascular unit dysfunction in neuronal death and cognitive decline has been indicated. In relation to dementia, the role of astrocytes, the essential cell type in maintaining proper blood-brain barrier and brain function, in A β deposition and clearance is still under investigation (Jo et al., 2014). However, it is known that astrocytes can contribute to neuroinflammation in stroke and AD (Pluta et al., 2018). During brain dysfunction, astrogliosis occurs, followed by an upregulation of the expression of proinflammatory cytokines and chemokines, which are associated with the pathogenesis of both, stroke and AD. Cytokines and chemokines play a role in neuroprotection and neurodegeneration as well,

in the brain. Inflammatory molecules can be either potential biomarkers for diagnosis or target molecules for therapeutic intervention. Understanding their roles and their relationship with activated astrocytes is particularly important for attenuating neuroinflammation in stroke and AD (Li et al., 2011).

During AD, A β , S100B and IL-1 β could accelerate A β generation in neurons leading to chronic neuroinflammation. Furthermore, astrocytes could be reactivated by TGF β 1 to generate more A β and to undergo the aggravating astrogliosis. On the other hand, following stroke, microglia and astrocytes are activated *via* Toll-like receptors (TLRs) (Liu et al., 2011; Wu et al., 2018), leading to up-regulation of nuclear factor kappa B (NF- κ B) (Zwagerman et al., 2010). NF- κ B has been well-documented to be a key regulator of both cell survival and inflammatory genes (Harari and Liao, 2010; Shih et al., 2015). NF- κ B induced inflammation has been shown to be triggered *via* TLR-mediated signaling, which ultimately promotes production of proinflammatory cytokines, such as IL-1 β , IL-6 and TNF- α (Shih et al., 2015; Wu et al., 2018). Thus, astrocytes as well are activated *via* different mechanisms in stroke and AD, hence contributing to the neuroinflammation as one of the hallmarks of both brain conditions. Indeed, anti-inflammatory approaches have proven to be beneficial in the prevention and treatment of stroke and AD-like neuropathology *in vivo* (Koistinaho and Koistinaho, 2005). Still development of effective anti-inflammatory drugs is needed for the therapies of stroke and AD (Wu et al., 2018).

As expected, there are many similarities in molecular mechanisms of neuronal cell death observed in stroke and AD. The neuronal transmembrane potential and ion gradient are disturbed at very early stage of both disorders. Stroke and AD share a number of overlapping mechanisms of neuron loss and dysfunction, including those induced by the extensive activation of glutamate NMDA receptors (NMDARs). Their overactivation with their appreciable Ca²⁺ permeability, leads to neurotoxicity in the cortex and hippocampus. NMDARs have therefore been therapeutic targets in both brain conditions (Janac et al., 2008; Selakovic et al., 2010; Radenovic et al., 2011; MacDonald et al., 2013), but they have failed in the treatment of stroke, and there is limited rationale for using them in treating AD (MacDonald et al., 2013). From point of organelle damage, molecular events seen in stroke and AD are comparable. Mitochondrial and endoplasmic reticulum damage in both disorders share common pathological findings, such as activation of pro-apoptotic signals. Moreover, lysosomes play important roles in stroke and AD. The leakage of lysosomal enzymes can influence the fate of neurons under pathological conditions in both disorders (Hayashi et al., 2006).

Another common pathophysiological mechanism is oxidative stress. As a consequence of stroke, but particularly after reperfusion, reactive oxygen species (ROS) such as superoxide, hydrogen peroxide, hydroxyl radical, and NO are generated. Radicals react with virtually any cellular component (carbohydrates, amino acids, DNA and phospholipids) and cause direct damage. Free radicals trigger a damaging cycle in the mitochondria, with inhibition of electron transport mechanisms, leading to excess superoxide production and also to activation of mitochondrial permeability transition (mPT) (Hayashi et al., 2006). Besides impeding ATP production, through loss of mitochondrial potential (Korenic et al., 2014), mPT leads to mitochondrial swelling and release of pro-apoptotic molecules (Hayashi et al., 2006). Oxidative stress is closely linked to excitotoxicity, energy loss and ionic imbalances, and all of these events contribute to brain tissue damage. Stroke involves a complex pathogenic cascade of events, which includes energy depletion, excitotoxicity, acidosis, peri-infarct

depolarization, neuroinflammation, and oxidative stress. Thus, the ideal treatment might need to make use of combined therapies (Dekanski et al., 2011; Radenovic et al., 2014).

In parallel, oxidative stress is considered to play a significant role in the onset and progression of AD. Transient hypoxia in AD can lead to mitochondrial dysfunction, impaired membrane integrity, and APP cleavage. During the progression of AD, lipid peroxidation, protein oxidation, and DNA oxidation have been reported (Hayashi et al., 2006). One of the major pathogens of AD - A β , can lead to inflammatory cell injury through a variety of routes. A β can not only precipitate a significant inflammatory response with microglial activation and the secretion of TNF- α , but also A β can elicit the neuronal expression of inducible NO-synthase, peroxynitrite production, and neuronal apoptosis during an acute inflammatory response. The generation of oxidative stress by microglia during A β deposition suggests that microglia play an important role in the pathogenesis of AD (Hayashi et al., 2006).

The possible therapeutic targets should be in connection with the common underlying pathophysiological mechanisms in stroke and AD, such as excitotoxicity, oxidative stress, neuroinflammation, and apoptosis. Thus, new and creative approaches are needed. In that view, natural products of diverse structures and pharmacological activities from marine organisms, were tested in stroke and AD models (Choi et al., 2015). It has also been shown that sphingolipids can act as bioactive molecules that control diverse cellular processes, such as proliferation, differentiation, growth, migration and apoptosis, and thus could be used in pre-clinical studies for the treatment of pathophysiological mechanisms underlying neurodegenerative diseases. Emerging evidence reveals that sphingomyelinase/ceramide pathway plays an important role in neurodegenerative diseases that involve mitochondrial dysfunction, oxidative stress and apoptosis (Chen et al., 2012). Minocycline, a semi-synthetic second-generation tetracycline derivative in clinical use for infection control, is also considered as an effective protective agent in various neurodegenerative diseases in pre-clinical studies. Since it acts *via* multiple mechanisms including anti-inflammatory, anti-oxidative and anti-apoptotic effects, minocycline is a desirable candidate for clinical trials in stroke and AD (Chen et al., 2012).

Several studies indicated that natural venom components can exhibit selectivity and affinity for a variety of targets in mammalian systems. For instance, natural peptides identified in venoms from animals such as snakes, scorpions, bees, and spiders, were shown to lessen inflammation, regulate glutamate release, modify neurotransmitter levels, block ion channel activation, decrease the number of protein aggregates, and increase the levels of neuroprotective factors (de Souza et al., 2018). Thus, these venom components have potential as therapeutic tools to slow neurodegeneration in post-stroke and AD brain. The diversity of the components in the venom of several animal species, as well as their high specificity to cell targets, contribute to making the pharmacological research of toxins a promising field (de Souza et al., 2018).

The limited capacity for neurogenesis in the human brain makes neurological conditions such as stroke and AD especially difficult to treat. Stem cell research has thus an important potential in the treatment of neurological diseases through cell replacement and stimulation of endogenous repair systems. However, there are still numerous questions that remain unanswered with regard to stem cell therapies including optimal cell type and dosage, mechanism of action, route of administration, long-term safety, etc. (Duncan and Valenzuela, 2017). The efficacy of stem cell therapies is also related to the extent to which the cells exhibit trophic factors, and other secreted therapeutic molecules (e.g., anti-inflammatory

chemokines and cytokines). While substantial progress has been made in neuroregenerative stem cell therapies, further investigation is needed to optimize them for clinical use (Tajiri et al., 2014).

Advances in induced pluripotent stem cell (iPSC) technology have the potential for development of so-called disease-in-a-dish personalised models to study disease mechanisms such as stroke and AD, and reveal new therapeutic approaches (Nair et al., 2017). Different cell types can also be produced for therapeutic use. In 2015, the US Food and Drug Administration granted new investigational drug approval for the first phase 2A clinical trial of ischemia-tolerant mesenchymal stem cells to treat AD. Similar trials are either underway or are being planned in Europe and Asia. Although safety and ethical concerns remain, there is a need for the acceleration of human stem cell-based translational research into potential treatments of AD (Hunsberger et al., 2016). The induction of functional subtype-specific neurons of the basal forebrain from endogenous non-neuronal cells by *in vivo* transdifferentiation might offer a novel mechanism for the reconstruction of degenerated neuronal circuits in AD (Smith et al., 2017).

Post-stroke acute brain injury typically peaks within 24 h of the insult, and reaches completion within 48 h. Due to the quick onset and short duration of acute brain injuries, potential neuroprotective therapies need to be administered early within 3–6 h of onset. This has proven to be challenging in the clinical setting. Any treatment outside of the 48 h window will offer no protection, and could instead be mainly restorative, targeting angiogenesis, neurogenesis, and synaptogenesis (Tajiri et al., 2014).

Finding a therapeutic approach that would delay the progressive secondary neurodegeneration will benefit stroke survivors. Hence, stem cell-based therapy has emerged as a potential treatment. To date, most cell transplantation studies have been conducted on animals during acute phase of post-stroke injury, leaving chronic time points understudied. Preclinical studies have demonstrated safety and efficacy of cell therapy in animal stroke models, while limited clinical trials provided solid safety and tolerability in stroke patients transplanted with human adult stem cells (bone marrow stromal cells; Acosta et al., 2015).

Recent advances in cell identity reprogramming have enabled investigation of the mechanisms of neuronal degeneration, as well as the mechanisms that govern age-related neurodegenerative disorders. Being early-stage biomedical technologies, stem cell-based reprogramming and transdifferentiation each face numerous challenges that limit clinical utility. As these limitations are overcome through refinement and innovation, diverse safe and efficient reprogramming methodologies will emerge to establish a new paradigm for patient-specific treatment of brain disorders such as stroke and AD (Smith et al., 2017).

In conclusion, new and creative approaches are needed for possible therapeutic targets, for stimulation of endogenous neurogenesis and synaptogenesis, as well as for exogenous neuroreplacement in stroke and AD.

Chapter 109

VIDEO-BASED QUANTIFICATION OF PATIENT'S COMPLIANCE DURING POST-STROKE VIRTUAL REALITY REHABILITATION

Matjaž Divjak, PhD, Simon Zelič, BSc
and Aleš Holobar, PhD*

System Software Laboratory,
Faculty of Electrical Engineering and Computer Science,
University of Maribor, Slovenia

ABSTRACT

We present a video-based monitoring system for the quantification of a patient's attention to visual feedback during robot assisted gait rehabilitation. The patient's face and facial features are detected online and used to estimate the approximate gaze direction. This gaze information is then used to calculate various metrics of the patient's attention. Results demonstrate that such unobtrusive video-based gaze tracking is feasible and that it can be used to support the assessment of patient's compliance with the rehabilitation therapy.

Keywords: video-based attention monitoring, gaze estimation, stroke rehabilitation, user compliance

INTRODUCTION

Stroke is the third most common cause of death in Western society, with about 4.7 million stroke survivors alive today. One of the hallmark residual impairments of stroke is

Email: matjaz.divjak@um.si.

post-stroke walking disability, which creates a stigma for patients, makes them more susceptible to injury and directly affects their quality of life. Early rehabilitation therapy is crucial for significant improvements (1). In recent years, robotic systems have been widely tested and employed to retrain stroke patients. By imposing gait-like movements at a comfortable speed, such robotic devices are thought to provide many of the afferent cues regarded as critical to the retraining of locomotion (2).

However, a major problem with existing stroke therapies is patient non-compliance (3). Many stroke patients abandon the therapy because the process is too long, repetitive, and/or does not provide immediate results (4). The European project BETTER (5) recently addressed a new approach to gait rehabilitation by employing non-invasive brain-neural computer interaction (BNCI) based assistive technologies based on EEG (Electroencephalography), EMG (Electromyography) and IMU (Inertial Measurement Unit) sensors. In this article, we extend the BNCI-based modalities with a video-based attention monitoring system that allows automatic quantification and long-term monitoring of user attention. Such attention tracking does not require any sensors to be attached to the patient, making this method easy and fast to apply in stroke rehabilitation. Our main objective is to quantify the patient's attention to visual feedback, i.e., the amount of time the patient's gaze is actively following the displayed visual feedback and to inspect the possible impact of visual feedback on motor planning, as well as its short- and mid-term benefits.

Several studies have already examined the impact of visual feedback on stroke rehabilitation, but they mostly reported inconclusive results. They focused on quantification of results of rehabilitation, enhanced with different kinds of visual feedback, but their experimental designs did not allow for a reliable quantification of the attention a person is paying to stimuli. To the best of our knowledge, only psycho-physiological measures of a patient's attention to visual feedback has been reported in (6), while video-based assessment of attention has not been proposed in the field of rehabilitation.

Methods for real-time detection of the face, facial features, eye movements and gaze direction from video have attracted a lot of research in the past decade (7). Numerous algorithms for facial feature extraction have been proposed, mostly in the context of face detection and recognition (8). Currently, the most promising approaches rely on fusing multiple visual cues, such as combining local feature matching with intensity-based methods (9). Existing methods for the quantification of user attention to visual feedback have mostly been developed for Human-Computer Interaction applications and in order to help severely disabled people (10).

METHODS

An overview of our approach is depicted in Figure 1. The patient is fixed in a robotic gait trainer, which moves the patient's legs according to predefined rehabilitation scenarios, and is adapted to the patient's current walking abilities. In front of the patient is a large TV screen showing various types of visual feedback. A high speed video camera is mounted above the TV. The camera captures HD video of the patient's face, while simultaneously EEG data are recorded from 51 scalp sites and EMG data are recorded from both legs (tibialis anterior muscle).

Figure 1. Overview of the proposed approach for video-based estimation of patient's attention/compliance during robot-enhanced rehabilitation.

The video streams are processed by our algorithms. First, frontal faces are detected and main facial features are extracted (corners of the eyes, pupil centers, mouth, tip of the nose). To suppress jitter from detection errors and body swings during walking, a Kalman filter is applied to the locations of the extracted facial features. Next, an active appearance model (AAM (11)) of the face with 59 facial landmarks is used to more accurately represent the current facial pose/expressions. The relative distances between extracted landmarks are used to calculate the head pose and gaze direction. Finally, different metrics of the patient's attention/compliance are computed: the percentage of time the patient is observing the visual feedback, the spatial gaze distribution maps, the responses to actions in the virtual reality (VR) environment, etc.

We tested five different types of visual feedback (see Figure 2): a calibration screen for the initialization of our algorithms; 2D plots of current leg positions; 2D plots of muscle activations; and two realistic VR environments (walking in a park from 1st and 3rd person perspectives). The VR environments were created in OpenGL 3.3 and consist of ground, sky dome and male/female avatars. The avatars were created in Mixamo Pro Character Creator Tool and animated with AutoDesk 3DS Max 2012. Both avatars have an underlying bone structure with all major joints modeled, allowing animation of almost all human movements. The actual avatar movement within the VR environment is controlled by kinematic data from the robotic trainer, so leg movements in VR world correspond with leg movements in real life.

The whole video processing system was designed for real-time operation, but the current version of the software is a mix of C++ and Matlab routines and runs at approximately 1 frame per second. Therefore, all video processing is currently performed offline, but (near) real-time operation is possible with further optimization of the code.

Figure 2. Five different types of visual feedback that are shown to the patient during therapy. Top row: the calibration screen for gaze direction estimation, and gait trainer's plots of current leg positions. Middle row: realistic VR environment from 1st and 3rd person perspective. Bottom row: special feedback displaying muscle activations.

EXPERIMENTAL RESULTS

The proposed system was evaluated in an experiment that involved 4 stroke patients and consisted of 5 runs of robot assisted walking with different forms of visual feedback. In all runs, the patients were instructed to walk actively, maintaining a constant speed, and applying minimum force on the robot. A 42" screen was placed in front of the patient, 1.4 m away from his face. Each run lasted 4 minutes. For all types of visual feedback the walking speed remained constant. During the experiments videos of the patient's face were recorded to disk in HD resolution and later processed offline.

On average, the face was detected in 93% of video frames recorded (i.e., in practically all the frames with frontal faces whereas the profile faces were not detected). Eyes, mouth, nose, and pupils were accurately detected in more than 99% of detected faces (see Table 1). Detection of facial features was skipped in video frames where no face was detected. The average jitter of detected facial features was 1.0 ± 0.4 pixels. The AAM was successfully fitted to all frontal faces. The average jitter of AAM landmarks was estimated at 0.6 ± 0.4 pixels.

Table 1. Facial feature detection performance, estimated on three test videos

	Video 1 (gaze targets)		Video 2 (gaze targets)		Video 3 (VR 3 rd person)	
	Frames	%	Frames	%	Frames	%
Whole video	9999	100%	13391	100%	10551	100%
Face detection	9833	93.7%	13193	98.5%	10427	98.8%
Detection of left eye	9805	99.7%*	13174	99.9%*	10419	99.9%*
Detection of right eye	9769	99.3%*	13179	99.9%*	10408	99.8%*
Detection of left pupil	9800	99.9%#	13191	99.9%#	10419	100%#
Detection of right pupil	9769	100%#	13187	100%#	10408	100%#
Detection of nose	9827	99.9%*	13150	99.8%*	10423	99.9%*
Detection of mouth	9742	99.1%*	13174	100%*	10414	99.8%*

* Values normalized by the number of face detections.

Values normalized by the number of eye detections.

Videos recorded during sessions with the screen displaying calibration targets were inspected by an expert and 9 approximate gaze directions (top-left, top-centre, top-right, bottom-left, bottom-centre, bottom right, left-centre, right-centre and centre of the screen) were manually annotated. The time periods corresponding to eye movements or eye blinks were ignored and were not annotated. Gaze direction was then calculated automatically by our algorithm and compared to the manually annotated gaze directions. The gaze directions were identified with average accuracy of $94\% \pm 6\%$. Most errors originated from distinguishing between top-left vs. bottom-left and top-right vs. bottom-right gaze directions.

Figure 3 shows an example of a patient’s detected level of attention to visual feedback, estimated as percentage of time, in 1 second intervals, with gaze fixed to the TV screen; all gazes outside the screen were classified as non-attention. Figure 4 presents an example of the estimated spatiotemporal gaze distribution metric. This metric shows relative frequency of identified gaze locations over a 4 minute long gait rehabilitation session. Brighter spots in the gaze distribution plots indicate areas with more frequent attention. Such maps support the identification of gaze targets (i.e., gaze hot-spots) and the assessment of spatiotemporal correlation between a patient’s attention to visual feedback and other BNCI-based performance indices of gait rehabilitation.

Figure 3. An example of estimated level of a patient’s attention to visual feedback during a 20 minutes long rehabilitation session (5×4 minutes).

Figure 4. An example of spatial gaze distribution plots (bottom row) for three different types of visual feedback (top row) shown to a patient during 4 minutes long gait rehabilitation sessions.

CONCLUSION

We developed and validated a video-based system for the robust tracking of a patient's face pose and gaze direction during robot-assisted lower limb rehabilitation therapy. The results (see Figures 3 and 4) show that such a system can be used to unobtrusively analyze patient's attention to displayed visual feedback and to provide a means for long-term quantification of visual feedback effects on the rehabilitation progress. It can also serve as an additional feature for other BNCI performance indices, such as similarity of motor modules, kinetic and kinematic profiles and brain patterns. For example, preliminary results show a significant correlation between attention to muscle activation plots and improvements in muscle activations during walking.

ACKNOWLEDGMENTS

This work was supported by the Commission of the European Union within Framework 7, grant agreement FP7-2009-7.2-247935 - "BETTER – Brain-Neural Computer Interaction for Evaluation and Testing of Physical Therapies in Stroke Rehabilitation of Gait Disorders." The authors would like to thank the personnel of Fondazione Santa Lucia in Rome, Italy, for organizing and performing the experimental recordings.

COLOUR-CHECK IN STROKE-REHABILITATION GAMES

***Veronika Szücs*, MSc, Cecília Sik Lanyi, PhD,
Ferenc Szabo, PhD and Peter Csuti, PhD***

Department of Electrical Engineering and Information Systems,
University of Pannonia, Veszprém, Hungary

ABSTRACT

This article presents the colorimetric testing of rehabilitation games designed for the StrokeBack project. In this testing, the main subject of the investigation was how the people with different colour-blindness types can perceive the games. Many programmers and game designers do not pay attention to the accessible aspect of games. This accessibility implies that users who are colour-blind should be able to use the games the same way as the people with no vision impairment.

Keywords: colour-check, rehabilitation game, stroke

INTRODUCTION

The purpose of the research described here is to investigate the colour palette of virtual reality (VR) based rehabilitation games (1), as designed for the ‘StrokeBack’ (2) project. The goal of the StrokeBack project is to improve the speed and quality of stroke recovery through the development of a telemedicine system which supports ambulant rehabilitation in home settings for stroke patients with minimal human intervention. During our investigation we designed our VR based rehabilitation games in such a way that they would also be enjoyable for people who have colour-blindness.

* Correspondence: Veronika Szucs, Department of Electrical Engineering and Information Systems, University of Pannonia, Veszprém, Hungary. Email: szucs@virt.uni-pannon.hu.

The disorders in colour vision can be inherited and acquired. The cones' red and green colour specific photoreceptor cells' genes are linked to the X chromosome. Because of the gender-linked inheritance, this type of impairment is 20 times more prevalent in men. About 8% of Caucasian males and 0.4–0.5% of females are “red-green” colour-blind. Inherited blue-blindness (tritanopia) is much rarer – only about 0.05% of the population can be detected. Some colour vision disorders are not inherited, they are so called “acquired”; several ophthalmological diseases can result in colour perception disorders (e.g., retinal diseases, glaucoma, cataracts, etc.) (3).

Stroke is a leading cause of death in the United States, killing nearly 130,000 Americans each year – that is 1 of every 20 deaths (4). Every year, about 800,000 people in the United States have a stroke. About 610,000 of these are first or new strokes; 185,000 are recurrent strokes. Evidence from opticians indicates that about 10% of the male population are colour-blind. This, together with stroke incidence rate, leads to a statistically important problem.

STATE OF THE ART

The harmony of colours and proportions play an essential role in the appearance. Although many tend to neglect these issues, numerous scientific research studies are concerned with this field. All this is based on the colour perception of the eye, which, however unconsciously, may have an influence on patients' decisions.

Scientists and artists over the last centuries (5–7) and nowadays (8) developed colour order systems where they defined rules to establish harmonic sets of colours. These colour harmony studies were based on the orderly arrangement of colours in the colour order system. The second group of authors (9, 10) defined colour harmony as an interrelationship of colours. The main principles of these studies are “complementary” and “analogous” but these concepts are not consistent among the studies. Also, the colour wheel was often adopted as a tool to define these basic relationships. Judd and Wyszecki (11) define colour harmony as a more universal concept: “when two or more colours seen in neighbouring areas produce a pleasing effect, they are said to produce colour harmony.” In addition, there is no consistency among the principles and the keywords of colour harmony: it is *completeness* according to Goethe (9), *order* according to Nemcsics (8) and Chevreul (10), and *balance* according to Munsell (6). A quantitative model for two-colour combinations based on the CIECAM02 colour appearance model was developed by Szabó et al. (12). Many other effects (i.e., age, cultural background) of colour harmony feeling have yet to be investigated.

In visual experiences, harmony is something that is pleasing to the eye. It engages the viewer and it creates an inner sense of order, a balance in the visual experience. When something is not harmonious, it is chaotic. At one extreme is a visual experience that is so bland that the viewer is not engaged. The human brain will reject under-stimulating information. The human brain rejects what it cannot organize, what it cannot understand. The visual task requires that we present a logical structure. Colour harmony delivers visual interest and a sense of order. Extreme unity leads to under-stimulation, extreme complexity leads to over-stimulation. Harmony is a dynamic equilibrium (13).

Colour deficiency is often neglected, as most people do not consider colour deficiency as a serious problem. Up to 15% of the population being affected by one form or another of

colour deficiency (13). It is quite common to see combinations of background and foreground colours that make web-pages, software, games etc. virtually unreadable for colour deficient users. Background, text, and graphics colours should be carefully chosen to allow understanding for people with colour deficiency. Designing for colour deficient people is complicated. It is not simply a matter of green/red or yellow/blue combinations (13).

The most important issue in designing for colour deficient users is not to rely on colour alone to convey information and not to use colour as a primary means to impart information (14).

METHODS

Currently 3 games are built in the StrokeBack project:

- Break the Bricks game: practices horizontal (right-left) wrist movements – the player's task is to control the object at the bottom of the monitor;
- Birdie game: practices vertical (up-down) wrist movements – the player's task is to make a little bird fly and not let it fall;
- Gardener game: practices finger extension movements – the player's task is to pump a virtual sprinkler to make the plants grow by watering them.

These games can be used during the home rehabilitation process by the patients or replacing/enhancing clinical rehabilitation, thereby speeding up the process of recovery. These games are single player games which the patient can play by himself/herself. It is expected that the patients will play more with the games than they would do exercises. To these games several 'locations' were developed:

- Break the Bricks: default bricks, car, cake, duck, ship, train.
- Birdie: default meadow, cave (played with a bat), circus, forest, jungle, mountain, sea, town, winter.
- Gardener: bluebell, carrot, currant, geranium, grape, pepper, rose, strawberry, tomato, tulip.

Figure 1. Gardener's "Bluebell" and "Grapes" themes as seen by a person with good vision.

Besides the 24 backgrounds for the 24 themes, more than 170 different objects had to be inserted, each of which had to be clearly visible. These were tested by different colour-blindness simulators and automatic testers.

Figure 1 shows two themes of Gardener as seen by a person with a good vision. Figure 2 presents the jungle theme of game Birdie and the objects that can be inserted as obstacles in the theme.

Figure 2. Jungle theme of “Birdie” game and the objects that can be inserted.

RESEARCH AND DEVELOPMENT

For the investigation four different colour-blindness simulators were used, which are accessible on the Internet and where pictures can be uploaded (15–17), and a downloadable software, ColorOracle (18), with which we could test the pictures appearing on the screen on the developer computer to find out how the users of different types of colour-blindness – deuteranopia, protanopia, tritanopia – see the colours.

Figure 3. Testing of “BTB basic brick” theme with ETRE simulator (left) and “Birdie jungle” theme with ASP.NET based online simulator (right).

Figure 4. Testing of “Gardener” with Coblis simulator (left) and “Birdie cave” theme with ColorOracle tester.

Testing and contribution to the field

Testing has been completed not only with the *ETRE*-, *ASP.NET* based-, and *Coblis*-simulators and the *ColorOracle* tester, but also with Variantor's special glasses (19), with two individuals with good vision, and two persons with colour-blindness. Based on prevalence (10%) of colour-blindness in the male population, and the case that colour-blindness is aggravated by stroke (20), individual tests using a standard colour chart display has been conducted. Figure 5 shows the difference between normal colour vision (Figure 5a) and colour blindness in the red tone (Figure 5b).

Figure 5. Original colour chart (left). Colour chart vision with Variantor glasses (right).

The tests were completed by people with normal vision and those with colour-blindness. The visual elements of the games were not just tested with online applications. Out of the possible test subjects, we filtered for colour-blindness by applying the Farnsworth-Munsell 100 HueColor Vision test (21).

During the test, the subjects had to look at some parts of images taken from the games and were then asked questions regarding them. The questions concentrated on visibility and perceptibility, and the elements disturbing or obstructing visibility and perceptibility. Example questions are:

- *Jungle theme*: What kind of fruits could you see on the tree? How many? Which animal has a darker colour?
- *Cave theme*: How many bats have been in the cave? What objects could you see on the ground beneath the crab?
- *Forest theme*: Was there a wooden high-stand in the picture? What colour are the mushroom caps? How many separate clouds are visible?
- *Winter theme*: How many white animals could you see in the picture? From which direction did the bird (if there has been) fly to the image?
- *General questions*: What value did the achievement bar show on the right hand side?

Based on the test subjects' opinion, the achievement bar has been placed on the periphery of the screen and for the most of the time they have not even noticed that it is placed there. In the test subjects' judgement, the games' visibility and perceptibility is good, although they

have indicated that, in the circus theme, the white and red stripes of the circus tent have been disturbing, which generated the vibrating effect. In the case where the recurrence of some image elements have been questioned, the elements have been recognized in the pictures and the subjects have even been able to determine the correct number, but the colours of the elements could not be recalled. As an example, in the garden topic the subjects were able to tell how many tulips have there been on the picture, but they could not tell the colours of the flowers. Responses to questions on colour balance include remarks that the plants in the picture mostly fade into the greenish hue background and, in case of the jungle theme, the green parrot can hardly be noticed between the leaves of the tree.

For some of the users and test subjects the noisiness and pixel problems due to the low image resolution were disturbing. The test subjects have also emphasized some situations that had disconcerting effects, for example when combinations of colours have been shown which physically interrupted the focusing of the eyes, as in the case of combination red-blue colours.

The results of the tests have shown that the observers – despite their colour vision deficiency – have seen picture elements taken from the game appropriately, the small details having been recognized and identified. The separation, observation and recalling of the games' image elements did not cause any problems for the validly colour-blind test subjects.

CONCLUSION AND PLANNED ACTIVITIES

We have not found any publications that consider the testing of colours of rehabilitation games, lending credence to our view that developers do not think about the colour-blind people. As a result of our testing, we reached the conclusion that, within the StrokeBack games, the objects are clearly visible, so the colour-blind patients can practice in the same way as the normal sighted. In future, games should not only be tested with the software, but also with other simulation goggles (tunnel-vision, macula or lens degeneration). Clinical tests of efficiency (which refer to the colour testing and efficiency of the rehabilitation) were started in June, 2014, and future reporting will detail these results.

Chapter 111

EVALUATION OF LEAP MOTION CONTROLLER AND OCULUS RIFT FOR VIRTUAL-REALITY-BASED UPPER LIMB STROKE REHABILITATION

***Dominic E Holmes*, BSc,
Darryl K Charles, PGCE, BEng, MSc, PhD,

Ulster University, UK

ABSTRACT

Intensive rehabilitation is important for stroke survivors but difficult to achieve due to limited access to rehabilitation therapy. We present a virtual reality rehabilitation system, Target Acquiring Exercise (TAGER), designed to supplement center-based rehabilitation therapy by providing engaging and personalized exercises. TAGER uses natural user interface devices, namely the Microsoft Kinect, Leap Motion and Myo armband, to track upper arm and body motion. Linear regression was applied to 3D user motion data using four popular forms of Fitts's law and each approach evaluated. While all four forms of Fitts's Law produced similar results and could model users adequately, it may be argued that a 3D tailored form provided the best fit. However, we propose that Fitts's Law may be more suitable as the basis of a more complex model to profile user performance. Evaluated by healthy users TAGER proved robust, with valuable lessons learned to inform future design. The majority of users enjoyed using the Leap Motion controller and VR Headset, the inclusion of visual cues shows a general improvement in target acquiring performance and that Fitts's Law can be used to linearly model user reaching and pointing movements in 3D environments. However, in some situations this

isn't the case, emphasizing the importance of user profiling to examine the user's kinematic behavior more intricately.

Keywords: virtual reality, leap motion, oculus, stroke, rehabilitation, usability

INTRODUCTION

Upper limb rehabilitation following a brain injury, stroke, or other condition affecting upper limb movement, is carried out by occupational therapists and physiotherapists to recover and adapt the patient's movement and improve activities of daily living (ADL). Research confirms that rehabilitation is capable of improving arm function during both the early and late phases of stroke. However, effective therapy must be intense and requires the repetitive practice of task-related movements and actions (1). Repetitive task training involves intensive repeated practice of appropriate functional tasks and is thought to reduce muscle weakness and form a physiological basis of motor learning (2).

Virtual reality (VR) has significant potential to support self-management of such rehabilitation, in that it allows individuals to interact and train within stimulating, realistic virtual environments. It provides users with the opportunity to practice intensive repetition of meaningful task-related activities necessary for effective rehabilitation (3). A recent Cochrane review of 12 trials involving 397 participants for the upper limb, stated that the use of VR and interactive video gaming might be beneficial in improving upper limb function and ADLs; when used as an adjunct to usual care or when compared with the same dose of conventional therapy (4). This Cochrane review concluded that it is unclear at present which characteristics of VR are most important. However, they emphasized the need for pilot studies assessing usability and validity as part of the development process if designing new VR programs for rehabilitation purposes; these studies may also afford insight on the key VR characteristics for retraining of movement e.g., in reach and pointing tasks.

In this paper we expand on our latest research (5), presenting a multi-sensory VR system, Target Acquiring Exercise (TAGER), and evaluate its usability and performance for upper limb rehabilitation. We evaluate Fitts's law as the basis of an adaptive system to model movement performance for reach and touch tasks in a 3D virtual space. TAGER evolved from previous VR and augmented reality (AR) testbeds developed by our research group (6) and particularly from initial research undertaken with the Leap Motion controller (7). TAGER utilizes several natural user interface (NUI) devices to track the user, namely the Leap Motion, Microsoft Kinect V2, and the Myo armband, and affords the option of wearing a VR headset (in this experiment the Oculus Rift DK1). In the experiment outlined in this paper, the tasks comprise basic 3D reaching and pointing exercises so we can effectively evaluate the system and user model. The experiment reported here focused on testing with healthy users to help us evaluate the user interface ahead of planned experiments with impaired users, and has helped us refine the user profiling system. A participatory approach to system and experimental design was taken; engaging with physiotherapists and occupational therapists in local health trusts, namely the Regional Acquired Brain Injury Unit (Musgrave Hospital, Belfast), the Stroke Unit at the Royal Victoria Hospital (Belfast), and third sector agencies, e.g., Brain Injury Matters (Belfast).

A core interest in VR as a rehabilitation tool is due to its potential to provide an enjoyable experience. However, VR systems are flexible technologies supporting feedback, capability adaptation, high intensity, repetitive, functional exercises to encourage motor control and motor learning. There are an increasing number of studies mainly focused on using commercially available hardware devices to support upper limb rehabilitation (4). Recent cheaper, high-quality commercial technology, such as Leap Motion and the Myo, offer new opportunities for effective, center and home based self-managed rehabilitation. When combined with other existing technology, they have the potential to improve accuracy and reliability of performance monitoring, although research utilising these technologies is still limited. Feedback is of particular importance to patients, and VR systems have the potential to excel in providing rich, informative, personalized, just-in-time responsive feedback. Feedback cues in VR environments, when appropriately designed, can help users improve interaction performance. Rehabilitation systems have implemented multi-modal cues such as visual, tactile and auditory cues. The organization of movement is related to the quality of the viewing environment, particularly visual cues between the user's arm and the objects to improve spatial awareness (8). Tactile cues have also been reported to improve motor performance (9), and are mainly used to help users verify a successful interaction. Positive auditory cues provide user motivation to perform intensified repetitive tasks, represent temporal and spatial information very well and can improve motor learning (10).

Adaptation is an important usability factor within a VR rehabilitation user interface design, to enable a system to adapt both to a diversity of motor control capabilities and as rehabilitation progresses (6). This capability to adapt is important as a user may become frustrated if the tasks are too difficult or bored if tasks are too easy; thus maintaining engagement is vital in rehabilitation. Techniques proposed in the literature for adaptive VR rehabilitation systems include fuzzy logic and Fitts's Law (11). Fitts's Law is well known in the user interface community and has also been applied within the stroke rehabilitation (12) context. Fitts's Law models a user's motor skills by predicting the time to reach and touch a target based on a target's size (W) and the distance (D) from an origin (Eq. 1). The logarithmic element of the equation, known as the "Index of Difficulty" (ID), is used to quantify the difficulty of reaching a particular target. Thus, the movement time (MT) required to acquire a target is linearly dependent on ID , where smaller and further away objects are harder to attain.

$$MT = a + b \log_2 \left(2 \frac{D}{W} \right) \quad (1)$$

Equation 1 shows Fitts's original equation, but other researchers have devised variations of the equation to provide an improved model in different situations. Two popular adaptations of Fitts's Law are Shannon/McKenzie (eq. 2) and Welford (eq. 3), which were originally tailored to quantifying human movement behavior for 1D and 2D tasks. They have also been applied to 3D environments, but recently new forms of the equation have been devised to represent 3D interactive movements more accurately. Equation 4 (13) adapts Shannon/McKenzie (eq. 2) to include the addition of a movement direction parameter, to account for the consideration that MT is also dependent on the user's angle of motion (θ) on the Y axis from the origin to a target.

$$MT = a + b \log_2 \left(\frac{D}{W} + 1 \right) \quad (2)$$

$$MT = a + b \log_2 \left(\frac{D}{W} + 0.5 \right) \quad (3)$$

$$MT = a + b \log_2 \left(\frac{D}{W} + 1 \right) + \sin \theta \quad (4)$$

METHODS

The research described in this paper has an exploratory emphasis and focuses on investigating VR NUI design, particularly (i) the reliability of tracking systems and the modelling of user motion via Fitts's Law and its variants, (ii) the aesthetic design of multi-modal cues, and (iii) the usability and acceptability of the VR headset. The purpose of conducting this research – and the subsequent follow up with impaired users – is to ensure that the underlying interactive interface and adaptive motion tracking system is as robust as possible before adding further user interface elements, game components, and connected health systems. Ultimately our intention is that the system will be robust enough for unsupervised usage by stroke patients.

Participant recruitment

Healthy participants were enrolled in the experiment from students and staff at Ulster University. Inclusion criteria included that participants should be 18 years old and over, have no vision issues (e.g., blurred vision, color distortion, light sensitivity, depth perception), nor any disability that affected the upper extremity. Participants completed a questionnaire to gather information regarding IT and gaming literacy and to determine inclusion in the experiment.

Target acquiring exercise (TAGER)

TAGER is a custom designed 3D pointing exercise for upper limb rehabilitation, designed based on requirements from research (14) and clinician involvement. TAGER utilizes a number of technologies that work together to monitor and provide feedback to users while completing upper arm rehabilitation tasks. The Leap Motion controller is a small desktop NUI which contains an infrared camera specifically design to track fingers, hands and arms. It tracks up to 20 bones per hand, with 150° field of view and approximately 8ft³ of 3D interactive space. TAGER uses the Leap Motion as the main interactive device within the virtual world for tracking motion and facilitating target acquisition. Microsoft's Kinect V2 is similar to the Leap Motion, though instead of sensing hands it senses motion of the human skeleton. We collect data of all joints in the upper body in motion with the goal in a future version of providing guidance on suitable functional task movements and other factors. It is natural for a person with an affected limb to move their whole body forward rather than

extending their arm, especially if tired. As this would hinder improvement through the rehabilitation process, system feedback and guidance can be crucial. The Oculus Rift DK1 (VR Headset) contains a 7" screen with a resolution of 1280×800 (16:10 aspect ratio) and a 90° field of view and enables head positional and rotational tracking. User head motion controls the viewpoint within a virtual world. The Oculus is investigated in this experiment to determine if it is acceptable for use and could potentially be used to increase spatial awareness. The Myo armband slides onto a forearm, and uses electromyography (EMG) technology with eight medical grade EMG nodes attached, that read electrical signals from the muscles. The Myo armband also includes an accelerometer and gyroscope to track movement and orientation on the forearm. The use of the Myo armband here is to collect data to be stored for future studies helping identify changes in muscles, which could highlight factors such as fatigue and correctness of exercise. The Myo armband also includes tactile feedback capability, for example, vibrations on the skin, which are used to introduce tactile cues into the system.

Experimental setup

The experimental process comprised three stages: (i) a training stage which gives the participant ten minutes to familiarize themselves with the technology and practice interaction. The training tasks are very similar to the real trials. Through system testing and observing users before the actual experiment it was decided that ten minutes training would be sufficient time for the participant to familiarize themselves but not cause fatigue. After training, the patients are given a short two minutes' rest period before the next stage (ii), which is the complete TAGER trial. In stage 3, after each user completes the trial, a short discussion takes place gathering any comments the participant might have and for the investigator to ask questions related to the user's experience of the system. Throughout the experiment, the participant was closely monitored by the investigator who provided assistance if any problems arose. The experiment was strictly controlled; the location of each trial was always the same as was the equipment used. Equipment arrangement was identical for each patient ensuring no other possible variables could affect the collected results. Figure 1 illustrates the layout of the environment.

Figure 1. The Experiment setup showing the equipment locations and typically user interactions.

Figure 2. TAGER's level layout and scene attributes.

TAGER's 3D virtual environment is the inside of a basic walled room (no wall at the front) with a large start button on its floor. The user was prompted to push the button with their virtual hand to begin. An icosahedron shape was purposely chosen as the target object for its geometric properties, especially since visual cues are required to enhance spatial awareness. With changes in viewing angles, objects with a greater number of faces and edges such as icosahedrons, provide more clarity of visual cues (15). Each repetition (4 per level) contains 27 icosahedrons to target, all at different locations, a total of 108 per level (4×27). When the start button was pushed a single icosahedron appears randomly at any of the 27 locations. The user moves their virtual hand around the 3D environment touching each icosahedron that appears. When touched, the icosahedron disappeared, and another icosahedron appears on the floor of the room at the location of the start button. We call this object the origin; this approach was used to provide consistent movement trajectories. All objects were intentionally placed at fixed locations and at fixed distances from the user's view to simplify analysis.

The TAGER VR software for this research was constructed with ten levels; the first and last levels were identical enabling us to compare performance over the period of the session – considering learning and fatigue effects. All other levels were unique concerning scene attributes such as target object scale, multi-modal cues and VR headset use; to investigate the impact they had on user movement behavior (see Figure 2). Levels 2-9 were randomized per user to eliminate potential bias in the ordering; a rest period provided between each level and repetition. The unique levels comprise different combinations of scene attributes such as shadowing and proximity color change for visual cueing. Tactile cues were included using the Myo Armband where a vibration was sent to the user's arm upon successful target acquisition. We also changed the scale of the objects; objects were sized accordingly as 2, 3.5 and 5cm. Objects were scaled to discover the impact it has on cues. For example, larger objects were expected to give greater clarity to visual cues and thus quicker arm kinematics. These scene attributes helped build knowledge on the impact they have on arm kinematics, spatial awareness, movement speed and accuracy.

RESULTS

The above experiment was undertaken to investigate core aspects of TAGER. Data was recorded every tenth of a second from all input devices, and *MT* calculated and recorded to file automatically from tasks for analysis of the movement models. Of the 26 participants, three were excluded from data analysis due to missing data or system issues (loss of tracking).

Usability

Of the 26 participants, 77% reported that their experience using the VR headset was enjoyable, no motion sickness or other health-related effects were reported. 43% of people commented that they perceived their performance to have improved while wearing the headset, while 50% said that they needed time to adjust when first wearing the headset. We compared user performance between the VR headset and monitor use, with and without cues. We used a paired t-test to determine significant differences between users' average *MT* and found no significant difference between Cues ($T = 1.681$; $DOF = 21$; $p = 0.053$) or No Cues ($T = 1.591$; $DOF = 21$; $p = 0.063$). Though, there was a consistently slower user response when using the headset (Table 1). In other words, the participant's subjective experience was at odds with the objective measurement. Although this is not a significant issue so long as the effect is consistent among users, it is a consideration for future interaction design. Discussion with health professionals reinforced the importance of aesthetic cues in rehabilitation VR system design. We provided feedback on target proximity and acquisition through lighting and shading, as well as vibration from the Myo armband. Figure 3 shows variation in interaction difficulty with cues (C) or without cues (NC) for different sized objects (large – LRG, medium – MED and small – SML). While results were generally as expected – i.e., cues supported improved efficiency in target acquisition. It was not clear that cues improve performance for MED cue acquisition and more investigation is required. More detail will be covered on the effect of cues in the next sub-section.

**Table 1. The mean movement time comparing VR headset and PC monitor:
Cues(C), No cues (NC)**

Exercise	VR (NC)	Monitor (NC)	VR (C)	Monitor (C)
Mean MT (ms)	1174.2	1107.4	1165.0	1115.4
T-test P = (0.05)	0.063		0.053	

Figure 3. The variation of interaction difficulty arranged by the magnitude of the mean movement time.

An objective way to evaluate system feature effectiveness in TAGER is to record target acquisitions (hits) against movement times. A target has been successfully acquired when the user's hand collides with the surface of the target object without leaving the Leap Motion's detection area. Hits are classified as unsuccessful when the user's hand leaves the boundaries of the Leap Motion's detection area before hitting the target; users were required to return to within the boundaries to hit the target. Users could not progress until they acquired the current target, even after registering an unsuccessful hit. It was found that targets positioned at the center depth (relative to the user) were more successfully acquired – a mean of 29 successful hits per task over all participants (Front = 22, Back = 26). Closer objects appear to have been harder to attain, suggesting we may need to consider moving the minimum distance further away (along the z-axis) or move objects closer to the z-axis along the x and y-axes. The latter suggests a cone area (16) for object placement – with the cone pointing towards the user – rather than a cuboid (which maps well to the Leap Motion's detection area). This approach might account better for arm kinematic differences in attaining targets in close and far locations. Users attained targets in all sectors with reasonable success, though on average there were 31 (28%) unsuccessful acquisitions per level from a total of 108 targets. This may be considered to be quite high for healthy users; if the Leap Motion was mounted on the VR headset, changing position so that the leap camera is pointing forward (user's facing direction) could possibly provide a more natural interactive space, and reduce unsuccessful acquisitions. TAGER's experimental design implemented two identical levels one at the beginning and end of the experiment, enabling investigation of the potential learning effects indicated by improved performance or user fatigue resulting in performance decline. The mean completion times for all users for the start task was 1257.8ms while for end tasks the mean completion time was 1081.4ms suggesting that, despite having 10 minutes training time at the beginning, user performance significantly improved over the experiment ($T = 4.60$, $DOF = 21$, $p = 7.7E-05$). There are also some indications of fatigue (or loss of concentration) among several users. Analysis of experimental data in the next section enabled us to investigate the intricacy of user profiles.

Model effectiveness

As outlined earlier we recorded user motion data in reaching from an origin to touch an object target at various distances. Figure 4 shows the lines fitted to the data through regression for four well-known forms of Fitts's Law.

Table 2. The mean y-intercepts across each TAGER level for all forms of Fitts Law

EQ	SML (NC) (ms)	SML (C)	MED (NC)	MED (C)	LRG (NC)	LRG (C)	VR (NC)	VR (C)	Start	End	Overall Mean

Figure 4. Regression line from our data for the four popular variants of Fitts Law.

Figure 5. Murata's 3D model of movement for user 1023 while wearing the VR headset, plotting Index of Difficulty against the user's response time to successfully target medium sized objects. Depth (z-axis) is distinguished by 3 locations in the virtual world relative to the user: front (red diamonds), center (green squares), and back (purple crosses).

Tables 2 and 3 show the average regression values of the y-intercept and slope values for all participants. Murata's 3D equation (4) provides y-intercept values ranging from 196 to 363, which are more representative of human movement response (typically 200 to 300 ms); it also provided a more gradual gradient giving a more appropriate model of *MT* against *ID* (17). Thus, while all four equations provided similar results, we focused on Murata for further analysis. Figure 5 shows typical results while wearing the VR Headset with and without cues for medium sized targets and Murata's 3D form of Fitts's law.

In Figure 5 when cues are included, user 1023 seems to improve her performance shown by a more gradual slope (decrease in value), the y-intercept (reaction time) towards a better representation of the typical human reaction time values and R² correlations are very similar. This experiment was fundamentally exploratory in nature. We used Fitts's law and linear regression to develop a user model, which will help us understand how best to create an adaptive system that can personalize interactive tasks. Table 4 provides user profiles from a proposed model comprising parameters such as regression line data, statistics on the residuals of the line fit, task performance and user information. Considering the explicit performance metrics (hits, movement times), target hits provided an informative statistic, and capable users are readily distinguishable from less able. Only one person had a score of less than 500 /1080 with the lowest score 472. The highest score was 900, and the average score was 754.74. Mean successful hits per person rose from 73.91 at the start to 77.22 at the end from a total of 108. The mean percentage improvement in hits over the experiment was 6.92% illustrating diversity of learning and fatigue effects among participants. The mean percentage reduction in MT was 13.79%. The average change in line fit according to R² and associated values were not significant (due to the spread of data values there are several valid lines). Change in hits

between the start and end tasks in the experiment were potentially revealing of a possible learning effect (improvement) or mental/physical fatigue. A learning effect provided a challenge to adapting task difficulty per user – it is preferable to adapt difficulty based on Fitts's law only after the learning effect stabilizes. Nonetheless, it was helpful to identify that a user remains in a learning phase so that additional support can be provided. However, MT and hits should not be considered independently, as some users may slow down deliberately to improve hit performance. The mean slope gradient decreased by 26.85% and the mean intercept decreased by 29.82%. Shallower slopes indicated a more skilled response as there is less difference between acquiring close and far objects, while a rise in the intercept value moves the intercept closer to physiological reflex norms (generally between 200 and 300ms). Additional user profile information can be gained from the residual statistics of regression lines and the changes between start and end tasks. Mean standard deviation dropped by 19.28% and mean variance also fell by 32.49%, suggesting that on average users were becoming more accurate. Range dropped by 10%, supporting this proposal. Kurtosis of residuals increased by over six times the magnitude (positive values) suggesting an increased number of data points with a small deviation from the regression line. On the other hand, skew also increased 44.4% (also positive), which after examining the regression graphs of users we believe was due to users overshooting the target position and having to change direction. From our results, we did not identify a strong relationship between performance and user age or gender.

Data from seven of the twenty-three participants provided a poor fit to the model based on start task motion data. Data after the end session from five participants had a poor regression fit, though two of these participants were different from the seven identified from the start data. These two people may have been overly tired or bored, rather than being less capable, highlighting the need for intricacy and careful analysis of the profiles. To consider this further it was necessary to examine a few representative individual user profiles (Table 4). User 1026 was an informative example, who started well with a strong profile but whose hits and mean MT declined significantly during the end task. Despite having residual statistics during the end task that show less variability (indicating more effective target acquisition for a significant number of targets), hit score actually decreased, while skew and kurtosis both increased (suggesting more overshooting of the target), and R^2 and the associated P-value suggested an unreliable regression fit (possibly due to an increase in outliers). 1026's mean MT dropped by a 23.96%, which suggested, considering the user profile, that during the end task this user may have adopted a high-risk strategy. This is in contrast to 1019, who appeared to have become more conservative, and by moving slower (13.64% increase in mean MT) improved their hit score by 12.82%. This considered approach by user 1019 and other participants seemed to improve the likelihood that the user motion data corresponds to Fitts's law (and variants). User 1002 had the weakest start having the lowest number of hits in the initial task but improved hit performance by 50% and mean MT by 31.59%. However, even by the end task, this user's motion could not be applied to Fitts's law reliably, and they had less than a 50% hit success rate in the final task. User 1023 exhibited arguably the most sustained success, having the highest overall hit success and start and end scores of 90 and 91 respectively and overall an improved profile (based on regression values). As with user 1019, 1023 was not particularly fast but improved speed during the experiment. Three participants got slower over the experiment and all of these achieved higher scores in doing so. Five participants got lower hit scores and all of these, but one had much less adequate regression

fit and three of these exhibited faster mean MTs. Further investigation is required to understand whether users with these profiles exhibit a decline of interest – the tasks were repetitive and several of these participants were quite skilled at the tasks – or due to mental/physical fatigue.

DISCUSSION

In this paper, we presented an initial version of the TAGER VR upper arm stroke rehabilitation system, which utilizes several inexpensive, commercially available input devices and a VR headset. We reported on an experiment that focused on the usability of the system and the use of various forms of Fitts's law to linearly model user motion - movement time against an index of difficulty – for reach and touch tasks in a 3D environment using a Leap Motion controller as an input device. Most users enjoyed using the Leap Motion device and perceived tasks to be easier with the VR headset on. No motion sickness or other negative health-related effects were reported. The importance of cues has been reported widely in the literature, and while our results show a general improvement in object acquisition with visual cues, we found the impact on targeting medium sized objects to be unclear. We outlined results from fitting user motion data to four forms of Fitts's law with each of the equations exhibiting a similar success. Examining the statistics of the regression process based on Fitts's law we found that these equations could be used to linearly model user motion with the Leap Motion controller in a range of setups including the utilization of a VR headset. However, the data point variance across the regressed line was quite high, and Fitts's law should not be applied as a simple linear model of user motion equally to all users. We recommend that a form of Fitts's law, for example, Murata's 3D version could be used as part of an intelligent system to profile users. Although the motion of most users could be modelled effectively using Fitts's law, we found a few users who found the NUI so difficult that they could not be modelled linearly. Most of these users required more training than we expected but in some cases, users appeared to become tired or bored. A more complex profiling system will help to identify training requirements and distinguish between loss of interest and mental or physical fatigue. We intend to develop the profiling system with further experiments and subsequently investigate the system with impaired users.

ABSTRACT

This paper describes strategy and work in progress. The combination of patient centered care where many care and nursing units are collaborating with focus on, and in concordance with the patient, the ability to project information focused on the patient's total situation and needs independent where the information was created, the ability to use sensor technology to collect a wide range of aspects of the individual's health situation, the ability to use sensor technology to assess movements both for assessment and intervention purposes, to keep the care and nursing process together through module based information services and a structured care plan containing goals, subgoals, defined activity types and a wide range of health status data involve great opportunities for patients having chronic diseases. This group of patients causes extensive resource consumption for society. Well-structured data and semantic definition of data is a key for the ability to communication between different types of multi-professionals actors with different background. New technology like a wide range of sensor types allows the possibly to catch large amounts of data both for assessment and intervention purposes in

* Corresponding Author's Email: johansson@alkit.se.

a continuous way over time. This research group has worked on these issues for several years and some important milestones have been reached. From a chronic point of view three groups of patients are focused: stroke patients, COPD patients and patients with Parkinson's disease. Collaboration approaches, communication technology and adapted information services allow new ways to perform home based care. Integrated monitoring services of planned activities like motion activities using 3D sensors allows professionals and patient to in an exact way follow planned and executed motion activities which is of great importance to many patient needs.

Keywords: serious gaming, rehabilitation, patient centered care process

INTRODUCTION

A stroke or any other neurological disease/damage, like Parkinson's disease, has profound impacts on a person's life. The conditions are often life long and require continuous treatment and rehabilitation, as well as support for the activities of daily life. Communication and the performance of assessment activities as well as intervention activities are tiresome and it is a challenge to create a care situation with continuity for the patient in order to achieve results. Due to the low physical mobility and poor overall condition of these patients, traveling back and forth to doctors, nurses and rehabilitation centres can be exhausting tasks. Communication and interaction with relatives and friends is important but often become cumbersome and may also include long, strenuous trips. More developed forms of home based care, in combination with support from various kinds of professional units, has great potential for innovation, with information technology as an enabler.

Rehabilitation is essential in order to promote and maintain maximal level of recovery by pushing the bounds of physical, emotional and cognitive impairments. It is the foundation to enable full reintegration into the society and pursued occupation. Assessment is a key component in the care of the neurological patient and important for both diagnostic and therapeutic purposes in clinical practice. Patients often perceive their experiences of rehabilitation care as non-connected or non-coherent over time. Continuity and early start for the patient regarding rehabilitation is important to reach constructive results.

For COPD patients the need and importance of performing exercise is similar. Performing exercise can aim at keeping existing capabilities of the individual and to contribute to the avoidance of exacerbation.

For many patients home based care can be an effective way to manage rehabilitation without being required to visit the hospital or other care unit when training has to be performed on a more daily basis. Video mediated remote strategies can be used to support and encourage the individual in being systematic regarding exercises for assessment and intervention purposes. Monitoring can be performed both by observing the individual, using video, but new possibilities are developed by using monitoring services which in detail can monitor how different movements have been performed using worked out representation approaches of sub-movements of each exercise type. Monitoring and storage of detailed results of each exercise instance can be used for feedback, visualization and analysis both for the patient and for the professional.

Stroke, Parkinson's and COPD are examples of diagnoses where movements are of great importance both for assessment and intervention purposes and some exercises can be used for

several diagnoses (1, 2), but many types of exercises should be quite different depending on function resources and disabilities of the individual. For example, for stroke patients the rehabilitation service should allow exercises where differences between left and right parts of the body functions are focused.

In earlier work we have documented experiences of developing telemedical tools, tools for support of rehabilitation activities, including, sensor monitoring, 3D visualization and haptics (3-5).

Experiences of this earlier work lead to the insight that:

1. Information services is needed to keep track of the whole set of relevant conditions and goals of the individual to be able to tailor personal plans which can encourage the individual to perform evidence based care activities
2. Be able to perform more of self-managed care activities
3. Make it possible to add new types of sensors and to use the values for them in a structured way so that analysis and conclusions can be drawn related to accepted health condition types and classifications
4. Being able to point out affordable packages of equipment and services which can be affordable to most patients

Games are assumed to stimulate and reward a person, and to make it fun and engaging to perform serious activities. The aim is often and to reach results in terms of keeping up to a structured and individual exercise plan. If exercise activities can be performed through games a lot of encouraging effects can be made. A lot of development work is being performed to create a workable representation structure so that a good representation of exercise types (and its sub-movements) can be associated with one or several game type alternatives. The user can choose between different games for the purpose to perform certain types of evidence based exercises important for the individual.

For Parkinson's disease we are developing tools for remote assessment of motor function. The underlying scientific procedure is called Movement Disorder Society-Sponsored Revision of the Unified Parkinson's Disease Rating Scale (MDS-UPDRS) (6): Process, Format, and Clinometric Testing Plan (7).

Recent work is focusing on monitoring, visualization and assessment of how the planned execution of the exercises really was executed. A specific monitoring part of the services has been developed that monitors and stores how every movement has been performed. This monitoring sub-service used the body representation and body posture to describe how every moment has been performed. Further, we have showed that depth cameras and other types of sensors are useful to follow movements (e.g., prescribed exercises) overtime and can provide a measure of rehabilitation progress in a wide range of remote health monitoring. The objective of this investigation is to develop tools and knowledge to identify if new technology matched with patient oriented services and new care procedures will lead to better rehabilitation in terms of both cost-effectiveness and quality for the individual. The overall goal is a multi-purpose, configurable ICT service platform supporting home based care highlighting the individual patient's specific needs.

Related to monitoring, one type of monitoring can consist of automatic collection of data concerning for example how an exercise has been performed, one other important type of monitoring is self-assessment by the individual him-/herself. For example, to COPD it is of

interest to collect data about how tiresome the performance of a particular exercise was experienced by the patient. For this purpose the Borg Scale can be used (8). Borg scale assessments must be linked to the exercise performance and to the elements of the sub-movements.

METHODS

3D sensors like the Kinect and other types of motion sensors like Leap Motion (LM) sensors are markerless motion capture systems which offer an attractive solution for home based rehabilitation (9). Although marker based tracking systems are more accurate, with spatial and temporal correspondence that marker less system lacks, the Kinect and LM devices' precision are sufficient enough for rehabilitation purposes (10, 11). The devices' accessibility and low cost render them an advantageous solution for home based rehabilitation. The video game environment provided by the sensors has the potential to become powerful motivation tools for performing regularly rehabilitation exercises. Data from tracking the execution of the exercises in real time can be used for assessment of patients' physical status, which can trigger the need for interventions. Furthermore, captured data can be utilized to provide guidelines to the user, thereby optimizing the effect of the exercise.

A promising approach, explored in some depth for stroke and COPD patients, is to integrate support for video-mediated communication into the rehabilitation support platform, which includes both LM and Kinect devices. The Kinect device is in this situation used both as a body tracking device and a camera, while the LM device is used for tracking of hand and finger movements. A therapist/doctor can thereby remotely assist or instruct the home cared patient, in cases where direct physical interaction is not needed. Related to patients with Parkinson's disease their motor performance will remotely be registered with the Kinect and LM sensors connected to a laptop or tablet computer. During the fall of 2013 we implemented one of the MDS-UPDRS procedure, namely "alternating movements" and tested it interactively with doctors and patients. Here the patient is instructed to repeatedly approach and remove the thumb and the index finger from each others as much and as fast as possible. For COPD patients there are similar challenges. One of the challenges is the importance of keeping up training and movements and repeatedly meet health care professionals for plan change and updates and also to meet relatives and friends to avoid depressions etc.

For several diagnoses, the risk of falls is significant and structured fall prevention activities are hence important. Many of the tools and technologies explored for Stroke, Parkinson's and COPD patients can also be used for fall prevention. Assessment, risk calculation and intervention activities can be designed to reduce the risk of falls, which can be beneficial for many kinds of home care.

RESULTS

From our previous experiences of stroke rehabilitation, we know that 3D sensor based approaches like Kinect works well in an interactive situation in assessing kinematic

information of motor function of the trunk, arm and leg. Now we have developed support for detection of hands and individual fingers. In most cases the interaction/instructions from the examiner can be pre-recorded 'machine' standards. Our preliminary study of the MDS-UPDRS indicates a drawback, namely that some tests must comprise a physical interaction or/and an, at the actual moment, individualized instructions from the therapist/doctor. In these cases, we have to develop alternative procedures or omit these parts. An added value, as compared to the clinically performed MDS-UPDRS, is that with the ICT tools we can assess kinematic, numerical, values specifying the tested functions. Examples are frequency of tremor, time/velocity/acceleration/precision in movements.

Further findings are that one has to structure the entire set of subservices to really take advantage of the technology potentials which can be used in the home. Development and tests have shown that the following parts are suitable:

- A component that can, in depth, represent a particular exercise type often consisting of a set of sub-movements. This includes variation variables for individual adaptation (see below),
- A component that allows the therapist to define which movement a patient should perform, including definition of regime, intensity, repetition, sets and adapted movements. This is part of the individual-ization and needs and goals for the individual,
- A component that can monitor and store how the patient actually is performing each particular movement at each particular occasion,
- A component that can represent all relevant health condition types and classification related to a set of diagnoses, over all goals, subgoals, goal values of health condition types and relevant relationships to activity types.
- A video-mediated communication tool designed for communication between a professional and a patient where the professionals really can see how different movements are performed in each planned session,
- A component that can describe game types and how they are related to evidence based exercise types.
- A follow-up module where results of each training session are visualized related to goals. This includes more exact monitoring of how each movement is performed by each body part monitored in real time.

To capture, store and analyze large amounts of data about how all exercises have been performed, approached based on Big Data analytics will be used. When monitoring every training instance, e.g., for COPD patients, it can be very fruitful to monitor and store all training instances including sub-movements and also simultaneously monitor medical sensor data such as blood oxygen saturation levels when performing a particular exercise. Based on the collected data, assessments can be performed and conclusions can be drawn about how that patient should perform certain types of exercises, resulting in an updated care plan.

Figure 1. Shows the distance between the index finger and the thumb on the x-axis with respect to the relative speed between the two fingers on the y-axis.

The following plot (Figure 1) shows the distance between the index finger and the thumb on the x-axis with respect to the relative speed between the two fingers on the y-axis. It shows an arc like concentration of dots which is what it typically looks like for a person without any disorder. The more a person is affected the more irregular and flat like are the plotted set of dots. This measure is an indicator of dysdiadochokinesia, the inability to perform rapid alternating movements, a sign of cerebellar and/or frontal cerebral lobe dysfunction. This kind of assessment can be accomplished by having the Leap Motion sensor attached to any home computer and having the patient simply surf to a web URL where the test can be carried out.

DISCUSSION

The work is in a development and exploration phase but soon more systematic comparative studies will be performed in order to measure effects. Fundamentally, the health cooperation concept is cross organizational process where different care and nursing units and actors can participate. The focus is the patient's overall situation and needs. All actors involved in different types of activities can access selected information in a distributed unit, based on the roles that they have related to the individual. The individual and relatives are heavily involved in the performance of the activities.

The platform architecture has two main parts: the service level and the sensor level. A large number of new sensors have been developed and new sensors will appear. Sensors are typically interpreted in relation to an assessment scale, reflecting a specific health care aspect.

The service level is concerned with the logical process oriented interpretation, computation, visualization and storage of data. This architecture will continuously allow new technology to be adapted and integrated. All activities are structured into activity types and activity instances. Some activities are aimed at assessment of conditions and some activities are aimed at interventions related to goals (that change with time). The health plan is an important concept keeping all assessment activities, goals and intervention activities together. The plan can contain prevention as well as assessment and intervention activities.

In this patient/person centric approach, specific e-services, involving sensor technology, can be used for development of other movement oriented health assessment and intervention activities, like prevention of fall injuries and training of motor functions aimed at restoring muscle performance or breathing capacity. The e-services will contain subparts like definition of particular movement oriented activity types, support of how a particular activity instance should be executed, recognition of results of a particular activity instance, reporting of results of an activity instance, video-mediated communication with professional and other actors for support of a particular activity instance. For many activity types, including stroke assessment and rehabilitation, COPD rehabilitation and fall prevention activities, whole body tracking is the most important. For the UPDRS assessment activities, high precision finger tracking is also required.

The tool set outlined here can also contain tool parts supporting powerful assessment scales like the ICF scale. (The International Classification of Functioning, Disability and Health) (WHO) for the purpose of make an extensive analysis and assessment of the situation of the individual. This support can also contain support for setting of goal values related to ICF and the selection of activities for the individual.

CONCLUSION

Sensors, computers, displays and communication technology is getting better and cheaper enabling advanced e-services for home based care, including real time support from remote medical professionals. The developed solutions can be both cost effective and provide high quality for the patients, due to improved continuity of care, less need for travel, and improved motivation to perform physical activities more often. This means that e-health services for home based care, including communication with healthcare professionals, have a great potential to overcome the challenge with increasing demands of care due to an aging population. The services must support both asynchronous communication of patient data, as well as real time interactions for monitoring, assessment, and support. Not only health care personnel, but also relatives and other informal cares need to be included in the communication. By designing an ICT platform supporting both synchronous and asynchronous communication of data from tracking devices and other sensors, including depth cameras and video cameras, a flexible and configurable multi-purpose care solution for home cared patients can be developed. Until such a sophisticated platform is realized, however, experiments with enabling technologies in specific patient groups must be performed, which is the objective of our present study.

ABSTRACT

Stroke and ensuing reperfusion injury is the third major cause of morbidity and mortality across the developed and developing nations. Neurological damage leads to cognitive impairment, a major deficit in behavioral, visual, sensory movement and muscle tone functions. In the absence of timely intervention, mortality seems to be the most common outcome of stroke incidence; however, restoration of blood flow does not guarantee complete recovery. Rehabilitation and post-injury management of stroke patient is the key to revive and ensure the normal functioning of the patient after stroke and reperfusion injury. Antioxidant supplements could enhance the chances of neurological and cognitive recovery while preventing further generation of free radicals responsible for cellular injury in massive stroke. Antioxidant actions are exhibited by agents obtained from an array of sources. This chapter shed light on various deleterious mechanisms of free radicals, its generation and available agents for restricting the cellular injury caused by the formation of reactive oxygen species (ROS) in stroke.

1. INTRODUCTION

Ischemic stroke is induced by permanent or transient obstruction of blood flow to any region of the brain which results in cellular and functional injury to cortex and hypothalamus. The obstruction of blood flow, in turn, results in deprivation of oxygen and glucose supply which instigate the cascade of major detrimental events responsible for cellular damage (Kalogeris et al., 2012; Carmichael et al., 2005). Similarly, restriction or obstruction of blood flow to any vital physiological organ lead to deprivation of oxygen and can result in severe

* Corresponding Author's Email: vvdhote@yahoo.com.

ischemic condition. Restoration of the blood flow to this deprived region is the pre-requisite to restrict and revive the cells at risk (Choi and Pile-Spellman, 2018). Paradoxically, this delayed restoration of blood supply through occluded blood vessels lead to debilitating consequences responsible for instigating severe metabolic energy deficiency, inflammation and leading to permanent loss of functional cellular activity. The extensive cell injury due to this late replenishment of the ischemic tissue or organ is termed as reperfusion injury (Aronowski et al., 1997; Verma et al., 2002). The intensity of ischemic insult and the period of deprivation of nutrients to cells determine the reversible or irreversible nature of stroke injury. This cell death can be characterized microscopically by extensive swelling which may include detrimental anatomical changes in affected tissue, deformed protein band and hypertrophic mitochondrial structure (Piper et al., 2004).

Ischemic reperfusion injury can occur to any of the major organs in the body due to various circumstances. However, brain and heart seem to be the most vulnerable organs to encounter damage due to abnormal variations in blood supply. This blood flow restriction could be transient which closely resembles clinical situations of vasospasm in a coronary artery, resulting in angina, or cerebral hemorrhage resulting in mild to moderate cellular damage (Kloner and Jennings, 2001; Kloner and Jennings, 2001). However, with prolong and severe ischemia, extensive loss of functional ability with an array of pathological implications to organ's normal physiology, collectively called reperfusion injury (Yellon et al., 2000). Stroke or cerebral reperfusion injury occurs due to development of obstructions in a small vessel or large artery resulting in neuronal cell death could be associated with vascular endothelial damage or vasospasm, dysregulated homeostatic mechanism and abnormal hemodynamic activity (Kalogeris et al., 2012).

In most of the developed and developing countries, cardiovascular diseases and stroke account for nearly 2/3 of the total mortality and morbidity cases. Half of the estimated 32 million patients with acute vascular dysfunction are those having pre-established coronary heart diseases (CHD) or major cerebrovascular diseases (CVD) (Saposnik et al., 2009; Hallenbeck and Dutka, 1990). The risk of CHD and CVD recurrence is highest among pre-exposed patients with cardiac and cerebral ischemic episodes. Stroke can lead to recurrence in survivors at about 7% per annum, while mortality is fivefold higher in patients with recurrent myocardial infarction than those without any predisposition to CHD (Saposnik et al., 2009).

In the USA, stroke incidences are regarded as the third most relevant cause of death or disability across all population groups. The economic and social burden entrusted by stroke drains national coffers by the estimated annual expenditure of \$ 23.2 billion. The alarming mortality rate from stroke, more than 1,50,000 deaths per year, baffles researcher world over. The enormity of stroke-related social and economic implications had ushered extensive investigation of neuroprotective agents. The rehabilitation of the stroke patient is crucial for complete recovery. One estimate highlight the plight of stroke survivors as 76% of them end up being disabled for the rest of their life (Carmichael, 2005; Shi and Wardlaw, 2016). A large chunk of \$53.5 billion expenditure is incurred by the cost of supportive measures required for long-term stroke survivors. Thus, stroke disables more than it kills. These facts and figures gave an impetus to recent efforts to develop strategies for neural repair and rehabilitation after stroke (Carmichael, 2005).

Oxidative stress generated by ROS regulates basic mechanisms of cellular dysfunction that occur during ischemia/reperfusion injury (Granger et al., 2015; Kloner and Jennings, 2001). Ischemia-reperfusion injury induced ROS can damage almost all vital cellular

components, including cellular membranes to nucleic acids of the cells in contentions (Marczin et al., 2003). The agents scavenging oxidative stress can be of exogenous and endogenous origin and these compounds generally termed as antioxidants, have multifaceted activity including scavenging of ROS, curtailing ROS generation by chelating various ions involved this process. Various endogenous antioxidant supplementations found to be beneficial in restoring the antioxidant enzymes during reperfusion injury (Pizzino et al., 2017; Hill et al., 2011). However, the exogenous supplementation of lipoic acid (Dong et al., 2015; Cao and Philis, 1995; Shmonin et al., 2012), coenzyme Q10 (Liang et al., 2017; Lu et al., 2017) was found to be protective in the reperfusion injury induced animals.

Numerous reports highlighted the potential of antioxidants and their combinations with other neuroprotective agents on the reperfusion injury of brain and heart. The studies emphasizing the role of antioxidants in the management of stroke would further help to clarify the controversies associated with the exact mechanism of antioxidants and its clinical applicability in ischemia/reperfusion injury. Herein, the chapter explores the multifaceted mechanisms involved in ischemia and reperfusion injury in the brain. The fundamental ROS generating mechanisms, as well as the endogenous scavenging tools for limiting the oxidative stress injury, are discussed in details. This section also provides an overview of the therapeutic as well as experimental approaches available for the treatment of cerebral stroke and reperfusion injury.

2. PATHOPHYSIOLOGICAL CONDITION RESPONSIBLE FOR PROGRESSION OF STROKE AND CEREBRAL INJURY

Cerebral infarction may result from one or more pathophysiological mechanism, which includes atherosclerosis, cardioembolism, reduced systemic pressure, hematological disorder, and metabolic disorder. The diseases of large arteries and small vessels along with channel disorders can also play a vital role in the initiation of cerebral damage.

2.1. Atherosclerosis

A pathological condition where lipids deposits, generally calcified on the innermost intimal wall of the blood vessel which in progression hardens these arteries is termed as atherosclerosis. Plaques develop especially at bifurcations of major arteries including carotid artery. The biochemical processes ranging from fatty acid to formation of streaks leading to plaque formation due to excessive proliferation of smooth muscle cells. Moreover, an already hardened wall narrow down lumen and obstructs blood flow (Al Kasab et al., 2018). This obstructing of blood flow leads to turbulence in blood and increases kinetic energy, which dislodges the plaque in the bloodstream. Thus obstructed and narrower blood vessels restrict blood flow sometimes resulting in thrombus formation. Of all stroke cases, almost 33% cases have an association with atherosclerotic thrombosis (Kannel et al., 1971).

2.2. Cardioembolic Stroke

Cardiovascular dysfunction leads to ischemic stroke. The common disorders are familial arterial myxomas, hereditary conduction defects and hypertrophic obstructive cardiomyopathy (Hassan et al., 2000).

2.3. Reduced Systemic Pressure

Multiple mechanisms responsible for stroke and related complications arise from obstruction of blood flow in cerebral arteries leading to ischemic damage in and around the localized region (Alloubani et al., 2018). Turbulent blood flow weakens the walls of cerebral and cardiac vessels. This would greatly affect normal hemodynamic functions and result in altered systemic pressure among vital arteries adding to the factors responsible for the development of ischemia (Hademenos and Massoud, 1997).

2.4. Hematological Disorders

Several mechanisms are suggested for the increased risk of ischemic cerebral stroke in patients with sickle cell disease; these include sickling of red blood cells during a crisis and thrombotic infarction of both large and small arteries (Ilesanmi, 2010). Patients with sickle cell anemia are more prone to develop stroke as compared to others.

2.5. Small Vessel Disease

In CNS, blood supply to deep white matter and basal ganglia is obstructed due to the structural changes in the small penetrating end arterioles is the hallmark of small vessel disease. Lacunar stroke syndrome is the most common clinical phenotype of this malformation. These lacunar infarcts may lead to cognitive impairment and disorder of gait (Shi and Wardlaw, 2016).

2.6. Vasospasm

Spasticity of subarachnoid spaces due to sudden and excessive bleeding coupled with muscular contractions is known as cerebral vasospasm. The vasospasm may aggravate focal constriction leading to total occlusion (Wilkins, 1988). Any cerebral blood vessel encountering vasospasm, for the varied time period, induces cerebral ischemia.

3. TREATMENT STRATEGIES FOR ACUTE ISCHEMIC CONDITIONS

Increased understanding of the biological implications of ischemic injury led to the development of various treatment strategies to limit the extent of injury in the subject. The

primary objective of the treatment is to assure immediate survival of the patient and to restrict the damage in critical ischemic condition. However, the major limitation of the current development is lack of ability to prevent cell injury in the sudden ischemic milieu. Initiation of necrotic and apoptotic cell death in core and penumbra is contributing to the neurological deficit and impaired locomotors activity. The current drug discovery and development efforts need to focus on recovery as well as management of the ischemic cells and related physiological functions (Zheng et al., 2006).

3.1. Management of Acute Ischemic Stroke

Evident neurological deficit and a history of abrupt onset of symptoms in the absence of trauma suggest the onset of a stroke. Restoration of blood flow to threatened vulnerable tissue incidentally before it progress to infarction presents realistic opportunity to salvage penumbral tissue (Kalogeris et al., 2012). The reperfusion therapies significantly restrict infarct area and provide a window to limit cognitive deficit as well as bring a marked improvement in neurological outcome. General treatment includes the administration of supplemental oxygen tissue and isotonic intravenous fluid and anti-thrombotic/fibrinolytic therapy (Snow, 2016).

3.1.1. Intravenous Thrombolytics

Tenecteplase (TNK), a genetically modified form of tissue plasminogen activator (tPA) is highly selective for fibrin and prevents any inhibition of plasminogen activator type 1. The long lifetime of TNK allows it to administer in a single bolus dose and its specificity to fibrin ensures complete clot lysis (Snow, 2016). Presently, desmoteplase, abundantly available in the saliva of vampire bats, *Desmodus rotundus*, induces faster recanalization than tPA and is clinically evaluated in phase 2 trials of ischemic stroke (Molina and Saver, 2005). A recombinant peptide developed from human tPA consists of kringle 2 and protease domains of human tPA and works as a potent recanalizing agent and this recombinant tPA is marketed as reteplase. Similarly, antagonists of glycoprotein (GP) IIb/IIIa are shown to have the ability to improve flow by dissolving platelet-rich clots in coronary and cerebral microcirculation (Molina and Saver, 2005; Snow, 2016).

Intra-arterial thrombolytic therapy can be performed with a microcatheter that is placed into, beyond, and proximal to the arterial occlusion. Urokinase is conventionally used while intraarterial tPA and prourokinase have been extensively studied in recent investigations (Snow, 2016).

3.1.2. Combined Pharmacological Approach

The combination therapy is put forth to expand the fibrinolysis time beyond 3 h. The combination therapies studied are anti-thrombotic (reteplase) and fibrinolytic (abciximab) provided faster, consistent and sustained reperfusion (Broussalis et al., 2012). Treatment with neuroprotective strategy (hypothermia) with thrombolytic (tPA) agent was promising. Neuroprotective stabilizes threatened tissue and extends the time window for the subsequent administration of reperfusion agent. The other neuroprotective strategies used in ischemia are glutamate receptor antagonist, calcium channel inhibitors and antioxidants (Mestre et al.,

2013; Molina and Saver, 2005). Administering agents that are vasoprotective (matrix metalloproteinase inhibitor batimastat) along with tPA may improve recanalization rates and improve the permissible time window for reperfusion therapy by enhancing the benefit/risk ratio in stroke as well as myocardial infarction incidences (Molina and Saver, 2005).

3.1.3. Sonothrombolysis

Although tPA is the most favored option in the management of ischemic stroke, its transportation and delivery to the site of thrombus are crucial to achieving desirable outcomes. Recent clinical evidence has demonstrated the ability of ultrasound technique to enhance enzymatic thrombolysis (Teng et al., 2017; Chen et al., 2014). Timely application of optimum frequency of ultrasound helps in transporting tPA into the thrombus and promoting the opening, cleavage of the fibrin polymers (Marczin et al., 2003).

Most of the strategies discussed above are aimed at providing the prompt and complete reperfusion of the severely ischemic tissue. Reperfusion injury is the paradox of recanalization of obstructed arteries resulting in major cellular dysfunctions (Aronowski et al., 1997). The recent research in stroke highlighted the implication of sudden reperfusion-induced cellular damage and hence the emphasis, in drug development for stroke treatment, is on understanding mechanisms of cell injury due to stroke and designing strategies to effectively counter reperfusion injury (Cuzzocrea et al., 2001).

In the last two decades, the research on reperfusion injury is revolving around the concept of oxidative stress management and the restoration of the metabolic balance of the cells prone to injury (Marczin et al., 2003; Cuzzocrea et al., 2001). Various herbs (Thiyagarajan and Sharma, 2004; Du and Ko, 2006), hormones (Zhai et al., 2000; Zhao et al., 2015) and chemical agents (Dong et al., 2015) were experimentally evaluated for its effect on reperfusion injury. Few of these agents were found to be effective but none of these could be taken to the next step of developing an ideal therapy for the reperfusion injury.

4. CROSSTALK BETWEEN OXIDATIVE STRESS AND CELLULAR INJURY

The impact of reperfusion injury related to ischemic myocardial and cerebral conditions is enormous and this enormity of the cerebrovascular and cardiovascular diseases has driven the scientific world in the pursuit of the ideal therapy or strategy to restrict the inflicted damage (Saposnik et al., 2009). Coronary heart diseases and coronary heart diseases take a heavy toll on the population of lower and middle-income group countries. Almost 75% of the CVD burden in the form of mortality and disability of the productive human resource is bore by this group of countries (Alves et al., 2016).

The scarcity of data makes more difficult to analyze the actual extent of these diseases in the developing countries. The major reason for the slow and agonizing progress towards developing an intervention to treat these pathological complications is the absence of a strategy for secondary prevention in CVD and CHD (Alves et al., 2016; Saposnik et al., 2009). The intriguing mechanisms of stroke have always been a quagmire for researchers as well as clinicians. Hence, the lack of therapeutic response to interventions targeting a single mechanism has warranted a study design that analyzes the approach of a combination of various pharmacologically active drugs. This approach gives us the liberty to study the effect

of multiple active drugs acting independently or synergistically in the combination to target more than one underlying mechanism in stroke or reperfusion injury (D'Ascenzo, 2015).

To start with, the extensive review of the mechanisms of injury involved in cerebral ischemia/reperfusion injury was carried out. Various factors assisting the ischemic damage and ensuing disability are discussed in detail while diagrammatic representation provides a view of ROS generation as shown in Figure 1.

Figure 1. Generation and metabolism of reactive oxygen species. Superoxide radical ($O_2^{\cdot-}$) is produced by ultraviolet radiations, stress, DNA damage, and atmospheric pollution. Superoxide is converted by superoxide dismutase (SOD) to H_2O_2 , which in turn is reduced to water by catalase and glutathione peroxidases (GPx). In the presence of Fenton reaction (iron and hydrogen peroxide are capable of oxidizing a wide range of substrates), H_2O_2 can undergo spontaneous conversion to hydroxyl radical ($OH^{\cdot}$), which is extremely reactive. GPx neutralizes hydrogen peroxide by taking hydrogen from GSH molecules resulting in two H_2O (water) and one GSSG. GPx oxidizes GSH to GSSH with the help of GR. SOD, Superoxide dismutase; CAT, Catalase; GPx, Glutathione peroxidase; H_2O_2 , Hydrogen peroxide; GSH, Glutathione; GR, Glutathione reductase; GSSH, Glutathione disulfide.

4.1. Oxidative Stress Induced by ROS Generation in Myocardial Reperfusion Injury

The myocardial injury is accentuated by the generation of free radicals from different sources during the process of reperfusion injury. ROS can be termed as any chemical species that contains one or more unpaired electrons in outer most orbit making the molecule unstable

and highly reactive. Hence it quickly gets coupled with an adjacent molecule by sharing an electron. This conjugation chemically modifies itself and also become excessively reactive owing to the availability of an extra electron. Consequently, the adjacent molecule follows the pattern of this oxidation and kick starts the chain reaction to generate ROS and in turn damage cell structures (Jennings and Steenbergen, 1985). The free radicals are generated in three ways:

1. Homolytic cleavage of the covalent bond
2. Loss of electron from a stable molecule
3. Addition of an electron to a stable molecule

This generation of free radical depends on the stimuli exerted to the cell. The ROS and others are generated by nitrogen termed as reactive nitrogen species (RNS) (Mimic-Oka et al., 1999). ROS can be divided into radicals and nonradicals. Radicals are superoxide radical ($O_2^{\cdot-}$), hydroxyl radical ($OH^{\cdot}$), peroxy radical ($RO_2^{\cdot}$) and alkoxy radical ($RO^{\cdot}$) come in this category. The nonradicals are hydrogen peroxide (H_2O_2), hypochlorous acid ($HOCl$) and singlet oxygen (1O_2). Nitric oxide (NO) and nitrogen dioxide (NO_2) are two major nitrogen species responsible for cell damage. The nonradicals in this category are nitrous oxide (HNO_2), peroxyxynitrite ($ONOO^{\cdot}$) and alkyl peroxyxynitrites ($ROONO$) (Cuzzocrea et al., 2001).

The initial surge in ROS generation during reperfusion has a unique mechanism and different source of generation than ischemic milieu. However, the exact source of ROS generation is not yet precisely identified but these cellular redox conditions are thought to be responsible for regulation of vital cell pathways (energy metabolism, survival/stress, and inflammatory reactivity). These are reports contesting conventional views about the exact role of ROS in cerebral as well as myocardial reperfusion injury (Marczin et al., 2003).

Generation of free radicals occurs when oxygen gets reduced through univalent pathway, however, the percentage of total oxygen reduction by univalent pathway is just 5%. Generally, the reduction of 95% oxygen is carried out by mitochondrial electron transport using tetravalent reduction pathway to H_2O where no ROS is produced. Superoxide anion is formed when oxygen accepts an electron and establishes equilibrium with protonated form $HO_2^{\cdot}$ which is favored and more reactive especially during ischemic acidosis conditions (Jones et al., 2003). Dismutation (SOD) of O_2 to H_2O_2 is the key to prevent potential oxidative cellular damage by $RO_2^{\cdot}$. Moreover, it is acknowledged that H_2O_2 is only directly toxic only at high concentration which is unlikely to occur under normal conditions. The cells have the endogenous mechanism to neutralize this formed H_2O_2 by catalase and glutathione system. Superoxide formed as a byproduct of the respiratory chain is safely neutralized to water. However, in ischemia/reperfusion condition this delicate balance is destabilized (Lefer and Granger, 2000). As the ischemia intensifies the defensive mechanism of the cells deplete and H_2O_2 become more empowered to generate the destructive hydroxyl radical ($OH^{\cdot}$) (Sugamura and Keaney, 2011). These hydroxyl radicals are highly reactive and are implicated in lipid peroxidation, destruction of protein as well as sulfhydryl bonds of the cellular structures. Similarly, metal ions like iron and copper are responsible for generating free radical. Especially the chelation of metals is considered to be an approach to reduce oxidative stress owing to the vital role played by iron and copper in oxidative stress-induced cellular damage (Jomova and Valko, 2011).

The Haber-Weiss reaction generates $\text{OH}\cdot$ from $\text{O}_2^{\cdot-}$ and H_2O_2 , accelerates the non-enzymatic oxidation of molecules such as epinephrine and glutathione (Jomova and Valko, 2011).

Oxidative stress induced by ROS generation during reperfusion injury is considered as a defining factor for exacerbating the cell injury in ischemia region of any vital organ (Pizzino et al., 2017). As the reintroduction of oxygen to ischemic cells produce oxygen free radicals after sequential reduction of the oxygen molecule, the formation of superoxide anion, hydroxyl radical, and peroxynitrite is envisaged in early first few minutes of reflow (Kalogeris et al., 2016). Other major contributing components in the generation of ROS are enzymes, such as xanthine oxidase, cytochrome oxidase, and cyclooxygenase, and the oxidation of catecholamines.

In addition to free oxygen radicals, reperfusion also increases inflammatory reactivity through activation of neutrophils (Vinten-Johansen, 2004), consequently, this infiltration of neutrophil also serves as stimuli for generation of ROS. Lipid peroxides are a precursor for lipid peroxidation which impairs functions of enzyme system which are bound to membranes (Rubbo et al., 1994). Poly-unsaturated lipids serve as a primary source of lipid peroxides after interaction with highly reactive free radicals. Endothelial dysfunction occurring in excessive oxidative stress can be traced back to improper release as well as the sensitivity of vessels to nitric oxides which may precipitate in microvascular dysfunction (Radi et al., 1991).

4.2. Key Mechanisms Responsible for Cellular Injury in Stroke

Few realms of disease are as devastating as neurological ones, because such damage can destroy our very essence of life. Stroke and following reperfusion injury is a major source of disability and thus much research is being placed on the treatment and prevention neurological well being (Snow, 2016). Various neuroprotective strategies include free radical scavengers, excitotoxicity inhibitors, and calcium channel blockers. Numerous new interventions are being investigated for the prevention of the severe damage caused by the cerebral reperfusion injury (Molina and Saver, 2005). To list, few of these are various hormones, tissue plasminogen activators and antibodies to adhesion molecules.

Pathogenetically, stroke integrates a heterogeneous group of diseases. Maximum incidences of stroke occur due to occlusion of vessels and account for 85% of all strokes, while few cases represent excessive intracerebral bleeding. Herein, emboli formation in arterio-arterial or cardiac origin is responsible for 75% of all cerebral vessel occlusions and resultant ischemic injury (Soler and Ruiz, 2010). In rare cases, approximately 5% cases of stenoses of cerebral arteries infarction may result in massive neurological deficit (Pongmoragot and Saposnik, 2012; Kumral et al., 2012). The reperfusion of ischemic brain brought by various interventions leads to cellular injury. There are numerous murine models for the induction of focal cerebral ischemia which resembles clinical ischemic stroke (Pant, et al., 2012).

Cellular injury in the brain following stroke is a consequence of multifactorial events occurring with a very short span of time. If the resourceful blood supply is not restored within

3 minutes of the recovery window the cells start experiencing energy deficit which generally ends up in cells resorting to apoptosis or even experience sudden necrotic damage (Piper et al., 2004; Kalogeris et al., 2012; Carmichael, 2005). Deficiency of oxygen and glucose to high demand organ like brain potentially reduces its functional ability and accumulates toxic metabolites which even induce structural damage to cells of the brain (Kalogeris et al., 2012; Granger and Kyietvs, 2015).

The duration and extent of deficient blood flow determine the changes and sometimes the reversibility/irreversibility of the damage to affected cells. Consequently, this situation regulates the intensity variables responsible for future changes (Aronowski et al., 1997). Alteration of electron transport and reduced ATP are two vital variables modulating the extent of blood flow reduction while ROS generation is the third one partially dependent on flow rate (Katsura et al., 1993). However, oxidative stress and ROS generation is a complex phenomenon which also includes the role of electron transport and available oxygen in its activation (Dirnagl et al., 1995). Hence it will be omnipresent even if blood flow is minimum, as slight as just above zero. Incidences of ischemia induce specific and extensive changes which result in cell death. The direct inhibition of oxidative phosphorylation is one of the most important activities in this cascade of events which include decreased pH, reduced ATP availability, ROS generation and increased accumulation of Na^+ leading to loss of ATP substrate for the $\text{Na}^+\text{-K}^+$ pump. The significant change in ionic concentration initiates secondary changes which finally result in damage of ischemic cells (Lipton, 1999).

Almost all focal ischemic models which closely resemble clinical settings involve occlusion of one middle cerebral artery (MCAO) (Ginsberg and Busto, 1989). The partial occlusion of blood flow with a nylon filament induces significant gradation of ischemia from the core of the lesion to penumbra which is an area at risk of cell death lying on the outermost boundary. The core and penumbra of the ischemic lesion exhibit different metabolic conditions within the affected ischemic site. Modification of MCAO can be achieved by coating the filament with poly-L-Lysine or silicon and inserting it into the carotid artery to be advanced at the origin of a middle cerebral artery. This technique generally ensures minimum variation in lesion size and blood flow restriction (Guan et al., 2012). With MCA occlusion and sudden reperfusion of the affected region induces large infarct area of 250 mm^3 at 24 h in rats (Guan et al., 2012; Koizumi et al., 1986; Aspey et al., 1998). Transient obstruction of blood flow increases the temperature in the core area up to 1.5°C due to reduced circulation and irreversible damage to hypothalamus as observed in Wistar rats. In addition, ischemia damages the endothelium of small arteries and also weakens muscles (Nishigaya et al., 1991). The core area of ischemic lesion comprises of the lateral portion of the caudate putamen and somatosensory cortex while the penumbra which can be revived consists of the neocortex and medial caudate-putamen (Belayev et al., 1997). The ischemia and reperfusion injury can affect the brain extensively and events involved in this injury revolve around the ionic balance and ROS generation.

5. MAJOR BIOCHEMICAL CHANGES AND CELLULAR MECHANISMS OF CEREBRAL INJURY

Detailed insight and molecular changes in ischemic cells can provide more information about the extent of injury as well as regulates the chances of recovery from initial insult due to severe ischemia in affected cells.

5.1. Ionic and Metabolic Changes in the Core and Penumbra

The biochemical and ionic changes triggered by stroke strikingly different in core and penumbra. These differences in metabolism strongly suggest a different mechanism for cell death in these two regions (Duverger et al., 1988). The infarct and edema in core and penumbra is the result of massive ion homeostasis disruption and the influx of water into cells of affected tissue (Back et al., 1995). The critical window of 1-3 minutes, experiencing rapid anoxic depolarization with a concomitant rise in extracellular K^+ to 70 mM and decrease Ca^{2+} at flow levels entering in a cell that is present in the core are critical for the cellular death (Martin et al., 1994). During the reperfusion period, after 2 h temporary focal ischemia, extracellular K^+ returns to control levels for 6 h before rising slightly or the remainder of a 24-h recirculation period (Gido et al., 1997). Despite this return to near normalcy, the insult produces severe damage in the form of infarct encompassing entire core (Fiolet and Baartscheer, 2000) and further development of tissue edema due to water influx in the cells. These changes account for the osmotic lysis and the lytic cell death is also referred to as necrosis, which is as a hallmark of the core of the infarct (Nagasawa and Kogure, 1989).

However, the limited damage to penumbra or risk of damage to the area receiving collateral blood supply through smaller arteries is due to lack of permanent anoxic depolarization with concomitant ion changes during the transient period (Back et al., 1995). Moreover, the ATP deficit, which generally maintained in this area at 50–70% of normal, do not fall enough to allow the anoxic depolarization. However, some transient depolarization (Ginsberg and Pulsinelli, 1994; Mizoue et al., 2015) actually originates from glutamate release in the infarct core but prompt reperfusion can salvage the area at risk of damage due to infarct.

5.2. Energy Metabolism in Stroke

The ATP levels in core fall to 25% of basal values and remain there between 5 min and 4 h of ischemia during transient ischemia (Folbergrova et al., 1992). The damage is severe even after restoring the ATP level up to two-thirds of the normal levels with 4 h of ischemic period. Whereas the ATP levels in penumbra remain around 50-70% of normal during this ischemic period (Folbergrova et al., 1995). The glucose utilization fluctuates during the early times and 3.5 h of the ischemia. During ischemia, the blood flows in penumbra declines but it is still much higher than that of the core. Glucose utilization in the cells of contention is one of the reliable indicators of the extent of the damage to core or penumbra (Belayev et al., 1997). Even after complete reperfusion, the required levels of ATP cannot be replenished to

their pre-ischemic values (Piper et al., 2003; Kalogeris et al., 2012). In some cells of penumbra glucose utilization is reduced to well below normal during early reperfusion, and if not restored the cells can later become part of the infarction (Robbins and Swanson, 2014). Reperfusion cannot guarantee prevention of damage despite the rapid recovery of ion homeostasis recovery by reoxygenation. Any single intervention is unable to limit or recover the damage to cells when ischemia lasts for 2-3 h. It will be advisable to administer drugs alone or in combination well before reperfusion to garner the maximum benefits of these interventions in stroke.

5.3. Free Radical Generation in Cerebral Reperfusion Injury

In normal conditions, homeostasis is maintained between free radical generation and elimination of it which is very well tolerated by the cells. However, ischemia-reperfusion injury represents a peculiar sequence of events leading to excessive generation of ROS like superoxide, hydrogen peroxides and hydroxyl radicals. Similarly, the scavenging activity of these ROS is deficient at the massive extent which ultimately leads to dysfunction of the cells in the event of increased oxidative stress (Hammer et al., 1993). Highly reactive peroxynitrite radical, generated from the reaction of superoxide and nitric oxide, can react with virtually any cellular component (carbohydrates amino acids, DNA, and phospholipids) and damage them (Iadecola, 1997).

5.3.1. Xanthine/Hypoxanthine Oxidation

Initial stages of ischemia, first 10 minutes after onset, lead to the breakdown of adenine nucleotides which may be metabolized by xanthine oxidase (XO) or xanthine dehydrogenase (XDH). Out of these two, XDH converts adenine nucleotides to nontoxic metabolites but XO generates free radicals which are higher in the brain and other vital organs like liver and intestine (Kinuta et al., 1989). Generation of superoxide radical and hydrogen peroxide is expressed in the given reaction:

5.3.2. Nitric Oxide and Peroxynitrite Generation

Highly reactive peroxynitrite is formed as a result of the reaction between nitric oxide and superoxide which both appears to rise during focal ischemia. Neuronal or endothelial NOS generates NO by activation of Ca^{2+} /calmodulin in most neurons and endothelial cells (Dawson et al., 1994). This Ca^{2+} /calmodulin movement directly activates the NOS enzyme and may also remove a phosphorylation-induced block by activating calcineurin (Yan et al., 2004). During ischemic episode upregulation of both neuronal and inducible NOS initiates reactions resulting in the generation of peroxynitrite:

5.3.3. Eicosanoid Accumulation in Ischemic Brain Regions

Generation of eicosanoids is one more contributing factor for oxidative stress-induced damage. Accumulation of arachidonic acid, via cyclooxygenase (COX) or lipoxygenase (LOX) pathway, serves as a substrate for oxidative metabolism and produces superoxides and hydroxyl radicals (Katsuki and Okuda, 1995; Kontos, 1986; Ikeda and Long, 1990). Break down of phospholipids into Arachidonic acid is increased in ischemia manifold due to the presence of free fatty acid (FFA) which also results in an increased free radical generation (Au et al., 1985; Nakano et al., 1990). During transient ischemia activation of NOS and COX is closely related to ROS generation within 6-24 h period. Similarly, global ischemia also follows an identical path for the free radical generation. The iNOS is present in endothelial cells and invading neutrophils (Nakano et al., 1990), whereas the COX-2 regulated ROS generation in neurons. In the reperfusion phase of injury, COX-2 (prostaglandin H synthase) produces superoxide radicals and iNOS generated NO spearheads the destruction of affected cells. However different cells do have a mode of activation of NOS and COX enzymes (Ahmad et al., 2009; Beckman, 1994).

5.3.4. Ischemia-Induced Alteration in Mitochondrial Function

Free radicals are generated at a brisk pace by the organelles in mitochondria. When electron carried becomes highly reduced, as much as 2% of the total electrons undergo single-electron reduction of oxygen molecule ultimately forming superoxide (Freeman and Crapo, 1982). These reactions very prominently occur in focal ischemia. Accumulation of Ca^{2+} and opening of mitochondrial permeability transition pore (MPT) at some stage of ischemia assist in the generation of free radicals.

5.3.5. Role of Monoamine Accumulation

Monoamine oxidase metabolizes accumulated catecholamines to H_2O_2 within first 5 minutes of ischemia. Superoxide and NO together produce peroxynitrite which mediates much of its toxicity (Birben et al., 2012). Ischemia also brings down the pH of the cell which favors the generation of $\text{OH}^\cdot$ (Birben et al., 2012; Dirnagl et al., 1999) and also by free iron (Sun et al., 2018), as shown below in the reaction generally termed as Fenton reaction:

5.4. pH Changes during Stroke

Severe impairment of blood flow during cerebral ischemia leads to a decrease in intracellular pH (pHi) by 0.5-1 unit. Interestingly pHi at core falls to 6.6, 6.2, and 6.1 when blood flow is reduced to 25% at 10 min and to 10% by 3 and 4 h respectively. However, penumbra at the same time (3h after ischemia) had no significant change in pHi even after a 40% reduction in blood flow (Meyer et al., 1986). Cerebral damage could be exacerbated by this increased acidity due to change in the rate of ROS generation and hence the pH profile during reperfusion is a vital parameter as well as a major contributing factor. Early dip in pHi is associated with immediate blockade of oxidative phosphorylation and the glycolytic flux (Lemasters et al., 1996). Deficient ATP supply also activates glycolysis stemming leading to

increased lactate concentration as blood glucose increased and fall in pH_i (Banani et al., 2000). These events during focal termed as lactate–acidosis-hypothesis is frequently cited in order to explain the glucose paradox of cerebral ischemia and following cellular injury. The paradox is that there is experimental evidence that high supply of glucose, the most important source of energy of the brain, in cerebral ischemia surprisingly induces more damage instead of limiting it as would have expected due to replenishment of ATP during reperfusion. However, this view of paradox is contested by another school of thought (Payne et al., 2003).

5.5. Anoxic Depolarisation and Na⁺-K⁺ Pump in Cerebral Reperfusion Injury

Anoxic depolarization is the unique feature of anoxia/ischemia *in vivo*, this anoxic depolarisation is observed especially in the core region and not in the penumbra (Chen et al., 1993). The significant extracellular negative direct-current shift (10-30 mV) in cell bodies of the ischemic tissue is often accompanied by the precipitous decrease in extracellular Na⁺, Cl⁻ and Ca²⁺ and considered as a characteristic feature of this phenomenon. Anoxic depolarization needs ATP for its initiation and the condition like hypoglycemia where the rate of ATP depletion is increased in hippocampal slices shortens the time to anoxic depolarization (Lipton and Whittingham, 1984). The average value of ATP is 40% at the time of anoxic depolarization and the depolarization occurs within 5 sec of the time at which ATP suffered a precipitous fall (60-90 Sec). This anoxic depolarization is due to Na⁺-K⁺ pump inhibition as it is essentially independent of extracellular Ca⁺ but produces rapid changes in ion concentrations (Nishizawa, 2001). It is still to establish that the pump inhibition is indeed the basis for the anoxic depolarization but the shift in K⁺ could be responsible for the majority of the depolarization (Ferrazzano et al., 2011) and indicates that the neuronal damage is strongly correlated with depolarization (Kaminogo et al., 1998).

5.6. Inflammation in Reperfusion Injury

As discussed earlier iNOS and COX-2 enzyme do regulate inflammatory reactivity in cerebral ischemia but the role of cytokines generated from activated leukocytes play a crucial role in adhesion and transmigration in brain parenchyma. Within a few hours of onset of ischemia, the expression of adhesion molecules at the vascular endothelium and circulating leukocytes induces stroke-induced brain inflammation (Ahmad et al., 2009). Neutrophil granulocytes accumulation in the cerebral microvessels of the penumbra disrupts microcirculation. Similarly, activated leukocytes (granulocytes, monocyte/macrophages, lymphocytes) neurons and glial cells (astrocytes, microglia) produce cytokines and chemokine. TNF- α , IL-1, and IL-6 are proinflammatory, play an important role as mediators of the inflammatory phase (Del et al., 2000), while IL-1 β acts as a substrate for free radical generation and inflammation. Anti-inflammatory cytokines like TGF- β 1 and IL-10 downregulates inflammation and have a protective effect in the context of cerebral ischemia (Bogdan et al., 1992). The iNOS and especially COX-2, by means of the production of free oxygen radicals as well as prostanoids, have a more detrimental effect on the penumbral tissue (Del et al., 2000).

5.7. Phospholipid Metabolism

Phospholipids serve as a major tool for the execution of membrane function and signaling capabilities due to the presence of phosphoinositides (Zhang and Sun, 1995). During ischemic episodes, the breakdown of phospholipids increases the levels of FFA and potentially enhances the rate of ROS generation. The reperfusion, in turn, activates arachidonic acid and result in greater free radical formation. This upregulated arachidonic acid and FFA concentrations and observed in CA1 for more than 1 day after 5 min of ischemia (Abe et al. 1991). Total FFA was increased 4- to 10-fold between the first 15 min and the end of 60 min of MCA occlusion (Zhang and Sun, 1995). The concentration of FFA is dependent on the duration of the ischemic period and the onset of reperfusion.

Metabolism of phospholipids is coupled with large Ca^{2+} influx and energy failures. In addition to energy failure, activation COX and free radical generation during cerebral ischemia present a conducive environment to initiate apoptosis (Rao et al., 1999). It also activates the platelet activating factor which is also responsible for the explicit increase in Ca^{2+} in neurons. The membrane damage induced by this phospholipids break down is of importance in an organelle other than plasmalemma (e.g., mitochondria). Even the loss in phospholipids content is small in the nonmitochondrial membrane may be small but the studies emphasize the importance of membrane damage (Fukai et al., 2011).

5.8. Permeability of Blood-Brain Barrier in Stroke

The integrity of the blood-brain barrier (BBB) depends on the interaction of the cellular matrix, which is composed of endothelial cells and astrocytes. Because of cerebral ischemia, this cellular matrix and the intercellular signal exchange is damaged. Proteases, especially matrix-metalloproteases (MMPs) play an important role in the disruption of the basic fabric of BBB. Upregulation of MMP-9 in endothelial cells during the first 24 h of permanent ischemia, is a result of cytokines production (Gottlieb, 2011) while extracellular edema development is due to activation of Na^+ transport across the BBB (Simard et al., 2007). Inflammatory reactivity increases temperature and as BBB is highly sensitive to temperature variation and this temperature sensitive nature of BBB causes extensive brain damage to endothelial tight junctions. Once the permeability of BBB is increased the transfer of leukocyte recruitment mediators across, creates havoc with respect to cellular damage during ischemia in a rat model of stroke (Venkat et al., 2017).

5.9. Apoptosis

Although the majority of cell death stroke occurs due to necrosis but the role of apoptosis cannot be ignored (Buja et al., 1993; James, 1994). Apoptosis is programmed cell death in the event of deficient energy still aerobic state of metabolism. Programmed cell death proceeds in a genetically programmed series of biochemical and morphological steps designed to avoid the indiscriminate release of cytosolic contents and the ensuing inflammatory response (Martin et al., 1994). The salient features of this type of cell death are chromatin condensation, endonuclease fragmentation of internucleosomal DNA to multiples of 180 to

200 base pair fragments, and cell fragmentation into small membrane-bound vesicles. On the other hand, necrosis, a catastrophic breakdown of cellular homeostasis occurs if oxygen supply crosses the minimum required level. It was however observed that apoptosis is an actively regulated process of cellular self-destruction, which requires energy and de novo gene expression, and which is directed by an inborn genetic program. The final result of this program is the fragmentation of nuclear DNA into typical nucleosomal ladder (Majno and Joris, 1995; Yuan et al., 2016).

Apoptosis, a programmed cell death takes place in a similar time frame as inflammation and involves caspase enzymes resulting in the development of characteristic histological features of apoptosis are membrane-blebbing, chromatin condensation, shrunken cytoplasm with intact organelles, apoptotic bodies in destructed cells (Majno and Joris, 1995; He and Simon, 2013).

Caspases are a unique class of aspartate-specific proteases (McIlwain et al., 2013), which targets nuclear proteins; proteins involved in signal transduction, and cytoskeletal targets (Yuan et al., 2016; Oliver and Vallette, 2005). Internucleosomal DNA fragmentation requires the prior cleavage of a cytoplasmic inhibitor of the apoptosis-specific endonuclease (inhibitor of caspase-activated DNase, DNA fragmentation factor) (Ktazumi and Tsukahara, 2011) and TNF- α mediated caspase activation (Teringova and Tousek, 2017; Kichev et al., 2014). Multiple isoforms of caspase especially, caspase 3 has a central part in the apoptotic signaling cascade, not only in cerebral ischemia (Friedlander, 2003).

DNA-repair enzymes like poly (ADP-ribose) polymerase (PARP) and DNA-dependent protein kinases (DNA-PK) are the substrates that are metabolized by caspase-3 (Friedlander, 2003). PARP identifies single strand disruption and mediate DNA-repair through the generation of ADP-ribose polymers. However, PARP reduces the energy pool of the cell because it consumes ATP. Although partially controversial, the use of ATP by PARP is considered cytotoxic (Yu et al., 2002). The cleavage of the inhibitor of caspase-activated DNase (ICAD) is of particular importance, as caspase-activated DNase (CAD) is activated by this mechanism. CAD leads to the characteristic DNA-laddering. Besides the destruction genetic information, structural proteins (e.g., laminin, actin, gelsolin) that are essential for the integrity of the nucleus and the cell are cleaved by caspases (Cao et al., 2001; Niizuma et al., 2010).

Antioxidants reduce the extent and rate of apoptosis, hence oxidative stress is expected to constitute an important intermediary step in signaling cascade of apoptosis (Ludwig et al., 1996). Apoptosis can be prevented by proteins or survival factors like interleukin-3, nerve growth factor (NGF), insulin-like growth factor-1 (IGF-1), or platelet-derived growth factor. Many neuroprotective agents like erythropoietin activate the PI 3K/Akt-pathway, plays an essential role in this neuroprotective pathway (Hernandez et al., 2017). Chromatin condensation and margination that result in a half-moon or horseshoe appearance of the nucleus are typical features of apoptotic cell death. The most commonly used techniques to detect apoptosis are based on the fact that during apoptosis the genomic DNA is cleaved within internucleosomal DNA segments by an endonuclease selectively activated during apoptosis (Lu et al., 2005).

6. MARKERS OF THE ISCHEMIA/REPERFUSION INJURY

Various mediators and their interrelated mechanisms accentuate the reperfusion injury. In the last few decades, the need for early prognosis of the injury was considered as a vital prerequisite for the treatment and the management of the reperfusion injury (Sinning et al., 2017; Kumral et al., 2012). The research was focused on the development of new markers of the injury for a proper clinical approach to avoid excessive damage and further complications. Few of the bio-indicators of the reperfusion injury are discussed in this section.

6.1. Oxidative Stress/Antioxidant Biomarkers

Oxidative stress caused by the production of free radicals is postulated as one of the earliest mechanisms for the damage to the tissue in the reperfusion injury (Robbins and Swanson, 2014). The generation of various ROS can be assessed by the measurement of endogenous antioxidant enzymes and the level of reduced glutathione. Lipid peroxidation during the injury is also of great importance to predict the damage caused by oxidative stress (Nakano et al., 1990).

6.1.1. Superoxide Dismutase

Oxygen, under normal conditions, is reduced to water (H_2O) by mitochondrial electron transport which reduces 95% of O_2 by tetravalent reduction to H_2O without any free radical intermediates (Sinning et al., 2017) while remaining 5% of oxygen is reduced via the univalent pathway ending up with free radicals production. Superoxide anion is generated after the acceptance of an electron by oxygen. Ischemia-induced acidosis alters the equilibrium of superoxide with its protonated form, $HO_2^\bullet$ and becomes more reactive. $HO_2^\bullet$ is capable of oxidative injury to fatty acids and cell membranes, which is presented within the cell by dismutation (primarily by superoxide dismutase) to hydrogen peroxide (H_2O_2). Under normal conditions, H_2O_2 does not occur in cells, which at higher concentrations is directly toxic to the cells. Cells do convert H_2O_2 to H_2O via catalase or glutathione system ensuring safe metabolism of superoxide, a byproduct of respiration to a humble water molecule (Dunning et al., 2013).

It is observed that a significant decrease in antioxidant enzymes especially superoxide dismutase (SOD) due to ischemic injury leaves affected tissue extremely vulnerable to oxidative stress-induced damage (Fukai and Ushio-Fukai, 2011). Superoxide is one of the most reactive ROS leading to oxidative stress and is generated at various stages of reperfusion following ischemia. SOD is an endogenous ROS scavenging enzyme which is subdivided based on the location where it is highly expressed. In the cytosolic and lysosomal fractions as well as in the mitochondrial intermembrane spaces has a maximum expression of CU/Zn-SOD (cytosolic or SOD1) (Okado and Fridovich, 2001). Similarly, inflammatory cytokines like $TNF-\alpha$, interleukins (IL-1 and 6) and interferon- γ (INF- γ) induce expression of MnSOD (mitochondrial or SOD2) in the mitochondrial matrix. However, overexpression of MnSOD has a protective effect on tissue against reperfusion injury (Ighodaro and Akinloye, 2001). In addition to these isoforms of SOD, brain exhibit extracellular SOD (EC-SOD also termed as

SOD3), a tetrameric protein secreted in extracellular compartment and is unregulated by iNOS after activation of NF κ B (Petersen et al., 2007; Qin et al., 2008).

Thus from all these data, it is clear that SOD enzyme has a critical pathophysiological role in the oxidative stress-induced damage and the mimetic of the SOD may have the clinical importance to restrict the injury.

6.1.2. Activity of Catalase

Hydrogen peroxide is produced by dismutation of superoxide by SOD. This hydrogen peroxide is moderately reactive and has the ability to freely cross lipid bi-layer of the cell (Lafon-Cazal et al., 1993). Hydrogen peroxide is converted to water, however, the intermediate hydroxyl radical formed is more reactive than hydrogen peroxide which is metabolized through the iron-catalyzed Haber–Weiss reaction (superoxide-driven Fenton chemistry) (Zweier and Talukder, 2006). Elimination of hydrogen peroxide is therefore critical to the efficacy of SOD in reducing oxidative stress. Catalase (CAT) and glutathione peroxidase (GPx) serve this purpose (Day, 2009). CAT is mainly localized to peroxisomes.

Thus catalase metabolizes H₂O₂, prevents possible lipid peroxidation. NADPH has a vital role in CAT activity during oxidative stress. NADPH assists CAT by preserving it from excessive H₂O₂ inactivation and provides a source of GPx during stress (Ighodaro and Akinloye, 2017).

6.1.3. Glutathione Depletion and Role of Glutathione Peroxidases

Glutathione is a tripeptide (g-L-glutamyl-L-cysteinyl-glycine) that is the reductant for glutathione peroxidase. This glutathione (GSH) which is made up of cysteine sulfhydryl group is vital for defense against oxidative injury. During ischemic insult, oxidation of the cysteine sulfhydryl group joins two GSH molecules with a disulfide bridge to form glutathione disulfide (GSSG). This oxidized metabolite is restricted as well as recovery of total GSH is catalyzed by NADPH dependent glutathione reductase. The ratio of GSH/GSSG determines the status of oxidative damage, higher the GSH/GSSG ratio smaller is the oxidative damage (Namba et al., 2001). Vital organs like the brain and heart maintain a high ratio of GSH/GSSG which ensures maximum antioxidant defenses in the event oxidative stress in the situations of ischemia and ensuing reperfusion. Even though the GSH/GSSG ratio is key to prevention of damage to the brain but severe depletion of GSH following ischemia/reperfusion may take up to 7 h to restore pre-ischemic values of GSH/GSSG ratio (Warner et al., 2004; Ozer et al., 2005; Namba et al., 2001; Dhalla et al., 2000). Principle consequence of GSH loss during oxidative stress in the brain is the formation of protein-glutathione mixed disulfides (PrSSG) and loss of protein thiols (Purucker et al., 1991). The loss of GSH and formation of PrSSG in the brain results in dysfunction of various membrane functions in cells, such as inhibition of Na⁺K⁺-ATPase activity and mitochondrial enzyme activities (Nakamura et al. 2000).

In this reaction reduced glutathione (GSH) is used as a co-substrate to metabolize H₂O₂, resulting in H₂O and oxidized glutathione (GSSG). Oxidized glutathione (GSSG) can be reduced back to GSH by the enzyme GSH reductase (GR), a reaction requiring NADPH regenerated by glucose 6-phosphate dehydrogenase (G6PDH). The capacity to recycle GSH makes the GSH cycle a pivotal antioxidant defense mechanism for cells and prevent the depletion of cellular thiols (Ighodaro and Akinloye, 2017; Day, 2009).

Glutathione reductase which removes GSSG recycles GSH and makes it available for reuse to avoid the stress injury. The individuals with GSH deficiency may well experience excessive oxidative injury as RBCs hemolysis and renders the endogenous defense system vulnerable to damage. Glutathione peroxidase overexpression was found to reduce the necrotic and apoptotic cell death in the cerebral injury. Various hydrophilic antioxidants (GSH and ascorbic acid) were protective on the myocardial ischemia-reperfusion injury (Ighodaro et al., 2017).

6.1.4. Lipid Peroxidation as Bio-Indicator

The brain has the liability of more easily peroxidizable fatty acids, which consumes a large quantum of total oxygen consumption. Except for a moderate expression of EC-SOD, brain lacks an enriched defensive antioxidant system (Schonfeld et al., 2013). Arachidonic acid concentration is at the highest level due to an increased flux of Ca^{2+} and ensuing energy failures during cerebral reperfusion injury causing damage to cellular membrane (Hendrickson et al., 1997). Inhibition of oxidative phosphorylation (Filmore et al., 2014), formation of proinflammatory mediators (Wang et al., 2016; Filmore et al., 2014), free radical generation and lipid peroxidation-mediated chain reactions (Sun et al., 2018), and cytotoxicity from lipid peroxidation products are major undesirable effects associated with FFA metabolism. These events may stimulate cell death in the vulnerable tissue, particularly in the penumbra region (Ramana et al., 2013). The extent of lipid peroxidation by any noxious stimuli can be measured by estimation of formed malondialdehyde (Grotto et al., 2009) which serves a reliable indicator of lipid peroxidation are shown in Figure 2.

Figure 2. Mechanism of lipid peroxidation. During the metabolism of oxygen, superoxide anion (O_2^-) is formed in presence of NADPH P450 reductase, further superoxide undergoes dismutation to hydrogen peroxide (H_2O_2). Myeloperoxidase (MPO) converts H_2O_2 to hypochlorous acid (HOCl), which is a strong oxidant that acts as a bactericidal agent. During Fenton reaction Fe^{2+} is oxidized to Fe^{3+} and H_2O_2 is converted in the highly reactive hydroxyl radical ($\text{OH}\cdot$), this radical result in lipid peroxidation.

6.2. Creatine Kinase

In search of the markers for ischemia and early predictors of infarct, creatine kinase (CK) was found to be a reliable marker of ischemic injury. Numerous reports considered depletion of CK in cardiac tissue and an index for infarction (Kitzenberg et al., 2016). CK is an important cellular enzyme mediating energy transduction in muscle cells. CK is highly sensitive to oxidation at the exposure of ROS due to the presence of SH groups in cardiac tissue. CK plays a key role in energy production and utilization by ensuring the availability of high energy phosphates throughout the cell (Kjekshus and Sobel, 1970; Saks et al., 1994). The rupture of myocardial cells and destruction of cellular integrity results in leakage of intracellular enzymes like CK from myofibrils after ischemic reperfusion injury. CK activity proved to be a pivotal cardiac marker due to its rapid appearance and marked an increase in serum after acute ischemia (Watts, 1973; Dreyfus et al., 1960). It appears that CK-MB is derived from the necrotic myocardial cells and levels of free release of CK indicate cell death. It was observed that CK release and its correlation with histology and ECG establishes a strong correlation to increased damage to myocardial tissue and is now considered to be a specific diagnostic tool in myocardial infarction (Al-Hadi et al., 2009).

Creatine kinase (MM and BB) is also found in brain tissue and may be elevated in the diseased condition. Mlinarik et al., (1998) studied the rate constants of the CK reaction in the brain after chronic ischemic condition. However, further research is required to establish CK as a reliable marker of cerebral reperfusion injury.

6.3. Myeloperoxidase

Myeloperoxidase (MPO), a polymorphonuclear neutrophil-derived heme protein, is a biomarker index for neutrophil infiltration and inflammatory reactivity. MPO activity is determined by an accumulation of neutrophils which are enhanced during insults like myocardial reperfusion injury is well established (Baldus et al., 2004; Stendahi et al., 1984; Matsuo et al., 1994). Recruitment of polymorphonuclear neutrophils (PMN) attributed to decreased bioavailability of nitric oxide (NO) is responsible for impaired microvascular functions. Whereas MPO facilitates oxidative NO consumption and impairs vascular function in animal models of acute inflammation. Upon activation, PMN not only generates superoxide and H_2O_2 but they also secrete MPO. MPO in the presence of H_2O_2 is anatomically poised to catalytically consume endothelial-derived NO; thereby impairing NO-dependent signaling in smooth muscle cells and subsequent vascular relaxation thus contributes in the endothelial dysfunction (Matsuo et al., 1994; Davies, 2011).

The molecular mechanism MPO mediated toxicity to the cell is halogenation and oxidation. Halogenation involves the covalent binding of the halide co-factor to the target cell or molecule. Among the possible products formed with protein acceptors and iodide as the cofactor are iodotyrosines, iodohistidines and sulfenyl iodides (Baldus et al, 2004). The presence of these chemical configurations near the active site could cause loss of biological activity of the cells. The oxidation may be mediated by such peroxidase system intermediates as halogens, hypohalous acid, chloramines, aldehydes, and singlet molecular oxygen. These MPO components react with extracellular halogen and damage the tissue in the vicinity of the

inflammatory response as the cell-free peroxidase system destroys leukocyte, platelets and other mammalian cells (Davies, 2011).

Increased brain MPO activity (in pericore region) after transient focal ischemia virtually reflects the neutrophil infiltration and this neutrophil infiltration into the ischemic brain is implicated in post-ischemic brain injury (which was evident from the histological observations) (Matsuo et al., 1994). Thus MPO can be considered as a biomarker to indicate the inflammatory response in the reperfusion injury of heart and brain.

6.4. Measurement of Plasma Fibrinogen

Ischemic injury due to obstruction of blood flow could be the result of inappropriate thrombus formation and profound exploration of links of thrombosis and risks of stroke or myocardial infarction suggested crosstalk between plasma fibrinogen and ischemia (Wilhelmsen et al., 1984). A synergistic effect of fibrinogen levels and blood pressure on stroke indicated high plasma fibrinogen is a risk factor for stroke and myocardial infarction (Stone and Thorpe, 1985). Thus, estimation of plasma fibrinogen could be a better diagnostic tool for exploring the thrombogenic potential of this protein in ischemic incidences and providing impetus to develop new strategies for the treatment and management of stroke (Gawaz et al., 2004).

7. PHARMACOLOGICAL STRATEGIES TO PROTECT THE REPERFUSED TISSUE

Maintaining and recovering the reperfused tissue is the foremost goal of the pharmacological interventions carried out during the reperfusion injury (Zheng et al., 2006). The objective of achieving the protection of the ischemic tissue must be:

- Restoration of obstructed blood flow to the ischemic tissue
- Limiting injury due to sudden reperfusion using interventions
- Reduction in intensity of damage due to reperfusion and restoration of cellular functions (Morel et al., 2012).

The goal mentioned to restore normal physiology of the ischemic and reperfused cells can be achieved by various approaches which include:

- Use of agents restricting ischemic damage also considered being anti-ischemic agents
- Ensuring complete restoration using reperfusion interventions
- Exploration and utilization of innate (adaptive) responses (Margaill et al., 2005; Morel et al., 2012).

7.1. Neuroprotection in Cerebral Reperfusion Injury

Injury score to ischemic stroke is highest in prolonging obstruction of blood flow; however, a narrow window of the first hour is available to achieve maximum neuroprotection. The recanalization within the first hour of ischemic onset is the best approach to rescue cells at risk of damage (Belayev et al., 1997). The most obvious target for achieving the goal of survival of cells, prevention of post-stroke complications and recurrence of stroke incidences are molecular mechanisms like glutamate accumulation, aberrant calcium fluxes, free radical formation and lipid peroxidation (Kalogeris et al., 2016).

Recanalisation of the blood vessel can be achieved by anti-thrombolytic, fibrinolytic and anti-platelet drugs which are already discussed in the stroke therapy section of the introduction chapter. Here, the neuroprotective therapy and the new advances in the treatment of stroke and reperfusion injury are mentioned.

7.2. Antioxidants and the Therapy Based on Antioxidant Markers

Oxidative stress which peaks after the reperfusion phase of ischemic tissue is considered to be a major culprit for the instigation and aggravation of the post-ischemic injury. Reperfusion is accompanied by the excessive release of glutamate and extensive infiltration of cells by neutrophil responsible for the generation of ROS (Vinten-Johansen, 2004; Matsuo et al, 1994).

Generated ROS amplify the profound imbalance found in the neurons and astroglial cells of the ischemic core and penumbra. Although tPA is approved for the treatment of stroke, very few treatments are clinically suitable as of now (Snow, 2016). Hence, considering antioxidant as the most promising therapeutic class available for the management as well as prevention of further damage in the ischemic cells enhances the chances of achieving the set goal of the treatment. Antioxidants have a longer therapeutic window than that of other strategies and can be economically viable options for the treatment. Stroke is considered as an outcome associated with a plethora of overlapping etiologies, strategies targeting multiple mechanisms with help of the combination of a various antioxidant could add on to the benefits individual therapy using right dose and correct timing for the administration of antioxidant agents. However, the translation of these antioxidants strategies in clinics still remains a distant dream (Dhalla et al., 2000)

7.2.1. Inhibition of Lipid Peroxidation

Inhibitors of lipid peroxidation are tested using tirilazad, a non-glucocorticoid steroid in first phase II trial (study of tirilazad mesylate in patients with acute ischemic stroke), while phase III studies were started as RANTTAS (randomized trial of tirilazad in acute stroke) (Johnston et al., 2002). The patients from North America were enrolled whereas patients from Europe, Israel, and New Zealand were tested for the parallel trial of the same agent (tirilazad efficacy stroke study). However, the results from most of these trials are not significant in reducing neuronal damage (Margaill et al., 2005).

7.2.2. Inhibition of Xanthine Oxidase

Allopurinol and oxypurinol were scrutinized for their antioxidant potential. Allopurinol is oxidized by xanthine oxidase to oxypurinol, which in turn brings about marked inhibition of xanthine oxidase by binding to the active site of xanthine oxidase inhibition (Nihei et al., 1989). Thus, allopurinol, as well as oxypurinol, can be administered with the same net mechanistic effect. The cerebral edema can be reduced by either of the agents as allopurinol decreases post-ischemic cerebral uric acid while xanthine and conjugated diene concentrations (Marro et al., 1994; Nihei et al., 1989), preserves ATP (Williams et al., 1992) preventing accumulation of fluid in affected cells (Van et al., 1998). The experimental outcomes of allopurinol in rats are mixed and a possible reason for this could be the inability of the agent to scavenge superoxide and hydrogen peroxide generated by other routes.

Many herbal agents found to have significant protective activity in stroke. *Curcuma longa* (Mohanty et al., 2004) and *Ginkgo biloba* (Clark et al., 2001), were studied for its effect on the murine models for stroke and further research is going on these herbs to develop an ideal herbal therapy for stroke.

7.2.3. SOD and Advance SOD Mimetics

The major endogenous SODs, which is studied widely for its effect on the ischemic brain are CuZn SOD, MnSOD and ECSOD (extracellular). Abundant availability of Cu-Zn-SOD and MnSOD in neural tissue had created major interest in the study of the modulation of these enzymes for the prevention of cellular damage (Ighodaro and Akinloye, 2001). Cu-Zn-SOD overexpression reduces ischemic damage resulting from ischemia/reperfusion (Yang et al., 1994). However, neither Cu-Zn-SOD overexpression nor Cu-Zn-SOD targeted deletion alter the outcome from permanent focal ischemia (Fujimura et al., 2001), indicating the requirement of reperfusion for this enzyme to play a role. Some studies highlighted the role of MnSOD in cellular activity after targeted deletion of this enzyme leading to worsening of the outcome from both temporary and permanent middle cerebral artery occlusion (Kim et al., 2002; Murakami et al., 1998). Similarly, over-expression of Cu-Zn-SOD contributed to inhibiting post-ischemic damage. EC-SOD overexpressing mice have increased tolerance to both focal and global cerebral ischemia, while EC-SOD knock-outs exhibit enhanced damage (Sheng et al., 1999). Administration of M40401, a SOD mimetic exhibited beneficial effects in gerbils (Mollace et al., 2003).

7.2.4. Catalase and Glutathione Peroxidase Activities

Catalase and glutathione peroxidase (GPx) are essential for the elimination of hydrogen peroxide generated during reperfusion. Although both enzymes are present in the brain the activity of GPx is sevenfold greater than that of catalase (Ighodaro and Akinloye, 2017). Further, while glutathione peroxidase is present in the cytosol, catalase is localized mainly in peroxisomes. Overexpression of GPx is implicated in significant reduction in necrotic and apoptotic cell death, astrocytic/microglial activation and neutrophil infiltration. Ebselen is a nonselective, synthetic mimetic of glutathione peroxidase (Muller et al., 1984) inhibits protein kinase C, 5-lipoxygenase, cyclooxygenase and NADPH oxidase (Schewe, 1995) is being studied in ongoing clinical trials (Saito et al., 1998; Yamaguchi et al., 1998). The Japanese Ebselen Study Group performed studies on the efficacy of ebselen in ischemic stroke and got approval for the treatment.

The other two antioxidants on the clinical trial at various phases are edaravone, a free radical scavenger, which delays infarct and edema evolution and decreased the mortality in acute stroke patients. However, improvement in functional recovery is not significant. NXY-059 is another free radical scavenger, which is studied in different continents and the results are encouraging. Its primary outcome is overall recovery and recovery of motor function (Green et al., 2003).

7.2.5. Nitric Oxide Synthase Inhibitor

Nitric oxide is synthesized by more than one isoforms of NOS, inhibition of any of these (eNOS, iNOS, and cNOS) affects the ability of NO to induce beneficial or detrimental effects. Pharmacologic eNOS inhibition would be expected to worsen outcome, secondary to cerebral vasoconstriction and reduced blood flow observed in eNOS-deficient mice (Lo et al., 1996) that have worsened ischemic outcomes. In contrast, upregulation of eNOS activity by treatment with 3-hydroxy-3-methylglutaryl (HMG)-CoA reductase inhibitors (e.g., simvastatin) caused increased intra-ischemic blood flow and reduced infarct size (Amin-Hanjani et al., 2001). Generation of peroxynitrite seems to be the major source of cellular damage and is correlated with upregulation of iNOS (Suzuki et al., 2002) hence inhibition of iNOS exhibited beneficial effects on ischemic injury in the brain.

7.3. Poly (ADP-ribose) Polymerase Inhibitors

Poly (ADP-ribose) polymerase (PARP) is an enzyme imparting a regenerating effect on nucleic acids after degradation of some codons or entire strands (Enders et al., 1997). Poly (ADP-ribose) is synthesized from NAD through a reaction catalyzed by PARP while its degradation is mediated by poly(ADP-ribose) glycohydrolase (PARG). The beneficial effect on that PARP knock-out on cerebral infarct in mice, when compared to wild-type counterparts, highlighted the possible role of PARP in neuroprotection (Eliasson et al., 1997).

DNA damage is a basic trigger for the activation of PARP which serves as a repair mechanism however it also results in NAD and ATP depletion which might potentially exacerbate the ischemic injury. As discussed earlier, peroxynitrite generation and its activity is a principal source of DNA damage (Giovannelli et al., 2002; Mandir et al., 2000). Interestingly, Cu-Zn-SOD overexpressing mice do not exhibit post-ischemic PARP activation suggesting that there is a close correlation between process involved in ROS generation and events leading to disruption of DNA strands or amino acid sequences in each strand. (Effects of pharmacological antioxidants on PARP activation have not been reported. It is warranted that any antioxidant having a major effect on PARP activation needs to be systematically evaluated in ischemic cell death or reperfusion injury. Antagonism of PARP or systemic administration of NAD could be a useful tool to improve ischemic outcomes under sudden reperfusion milieu (Yang et al., 2002).

7.4. Spin Traps Application

The spin trap is a method to capture ROS allowing their detection and quantification. Spin trap approach is first studied in the ischemic brain using salicylate, which reacts with hydroxyl radical to form a relatively stable adduct, 2,3-DHBA (Lapchak and Araujo, 2002). In order to establish this approach or restrict reperfusion injury, nitroxide spin probes, nitron spin traps were developed to capture ROS, allowing detection by electron paramagnetic spectroscopy. Recognizing the potential for nitrones to scavenge ROS, it was considered that these compounds might present therapeutic potential (Marshall et al., 2003). Indeed, administration of the spin trap α -phenyl-N-t-butyl-nitron (PBN) is reported to be protective against both global and focal ischemic insults. Moreover, the second generation spin trap, NXY-059 (disodium 4-[(tert-butylimino)-methyl]benzene-1,3-disulfonate N-oxide) has been found to improve ischemic outcome in primates even after 10 weeks of permanent occlusion of the middle cerebral artery, even when treatment was begun as late as 4 h after onset of ischemia (Marshall et al., 2003). NXY-059 has been shown to maintain Akt activation and inhibit cytochrome c release after ischemia (Yoshimoto et al., 2002).

7.5. Glutamate Antagonists

Glutamate-induced excitotoxicity is implicated in the reperfusion injury damage. Hence the neuroprotective therapy can avail one more avenue of glutamate antagonists. A new glycine-site NMDA receptor antagonist SM-31900 is a potent neuroprotective agent without adverse effects and indicates that it is a promising therapeutic for stroke (Ohtani et al., 2003; Hoque et al., 2016). SM-31900 exhibits nanomolar affinity for this receptor site and selectivity relative to other neurotransmitter receptors and ion channels. In rat models of transient and permanent focal cerebral ischemia, postischemic administration of SM-31900 significantly decreased infarct volume, with potency and efficacy superior to gavestinel, another glycine-site NMDA receptor antagonist. Unlike other NMDA receptor antagonists (dizocilpine, selfotel, eliprodil), neuroprotective doses of SM-31900 were not associated with adverse effects, such as psychotomimetic effects, neuronal vacuolization, renal toxicity or cardiovascular effects. (Prous Science, 2006). YM872, an AMPA receptor antagonist, is a neuroprotective compound that ameliorates the deterioration of the hemodynamic penumbra after focal ischemia (Shimizu et al., 1998).

7.6. Inhibition of Interleukins

Interleukin 1 (IL-1) receptor antagonist, anakinra treatment groups showed neuroprotection, particularly in the cortex, with a significant increase in the frequency of surviving cortical neurons. A nonsignificant reduction in the area of focal infarction in the striatum was also seen in the IL-1 receptor antagonist (IL-1ra)-treated groups (Emsley et al., 2005).

7.7. Matrix Metalloproteinases Inhibitors

Evidence implicates the involvement of matrix metalloproteinases (MMPs) in the disintegration of the vasculature and BBB disruption following cerebral ischemia (Misra et al., 2018). Investigators at University of California at San Diego examined the effects of pharmacological inhibition of MMPs with the relatively nonspecific inhibitor batimastat (BB-94; British Biotech) in a rabbit model of tPA-induced hemorrhage after thromboembolic stroke. This study reported that pretreatment with an MMP inhibitor may improve the safety of tPA in the management of acute stroke, preventing intracerebral hemorrhage, although further studies are necessary (Lopchack et al., 2000).

7.8. Heat Shock Proteins

Hypothalamus, especially CA1 and CA3 and dentate granule cells, exhibited strong expression of HSP70 and HSP72. Penumbra which is considered to be the region of cells with salvageable neurons due to collateral blood supply showed marked ability to produce HSP70 (Weinstein et al., 2004). It has been an intriguing correlation between the expression of HSP and resistance to ischemia in focal ischemia. Activation of the transcription factor NF- κ B, responsible for inflammatory reactivity during ischemia is inhibited by HSP expression in cells under ischemic insult. The 70-kDa HSP is proven to be highly protective and this effect could be attributed to protection against apoptosis, by blocking the downstream actions of caspases on activation of PLA₂, the cell nucleus, and other processes (Li et al. 1993; Sharp et al., 2013).

As established in previous approaches use of single therapeutic agents may show potential promise in animal models, its efficacy in the clinical setup is unconvincing. Consequently, exploration of combined therapeutic approaches in stroke is a need of hour owing to multifaceted etiology of stroke-related cell injury. Herein, it is worth to study various agents and evaluated their effects on reperfusion injury alone or in combination with various hormones. The selection of the agents is based on the antioxidant properties exhibited by the drug may offer promising clues for the management of stroke and other ischemic injuries (Margaill et al., 2005).

8. AGENTS WITH ESTABLISHED ANTIOXIDANT ACTIVITY IN REPERFUSION INJURY

This section highlights some of the agents considered therapeutically viable and are considered for experimental as well as clinical therapeutics.

8.1. Lipoic Acid

Lipoic acid (thioctic acid) is 1,2-dithiolane-3-pentanoic acid, is a molecule which contains two thiol groups and 1,2-dithiolane ring, first isolated from liver samples in the early

1950s. Dihydrolipoic acid and lipoic acid are the natural constituents of biological membranes, acting as mitochondrial lipoamide co-factor of α -ketoacid dehydrogenase (Richard et al., 2011; Panigrahi et al., 1996; Packer et al., 1995). Lipoic acid is highly protein bound by an amide linkage to a lysine residue; this linkage is called as lipoyl group, which plays a lead role in many multienzyme complexes (Packer et al., 1995).

A dual acting α -lipoic acid has the ability to act as an antioxidant in fat- and water-soluble tissues in both its oxidized and reduced forms. Its major advantage seems to be rapid absorption in GIT after oral administration and minimum undesirable changes in other gastrointestinal activity makes lipoic acid a potentially effective therapeutic agent in clinical conditions associated with free radical damage (Cardoso do Vale et al., 2003). Lipoic acid is reported to be an excellent antioxidant in studies and radially taken up by the cells. The exogenous α -lipoic acid is metabolized in the liver to where NADH and NADPH systems play a major role in intracellular conversion. Dihydrolipoic acid, the reduced product of lipoic acid produced in intracellular spaces acts as an antioxidant in extracellular space (Packer et al., 1995; Cardoso do Vale et al., 2003).

Rosenberg and Culik in (1959) discovered the ability of lipoic acid as a potent antioxidant when it exhibited protective effect in both scurvy symptoms in vitamin C-deficient guinea pigs and vitamin E deficiency in rats fed a diet lacking α -tocopherol (Chidlow et al., 2002, Packer et al., 1995; Sige et al., 1978).

Lipoic acid is studied for its antioxidant property in various models of ischemia and reperfusion injury. It found to have an antioxidant effect in cerebral ischemia-reperfusion injury owing to its ability to improve survival and protecting the rat brain against reperfusion injury following cerebral ischemia (Panigrahi et al., 1996). The mitochondria are the main site of antioxidant action of α -lipoic acid. The lipoic acid increases the intracellular glutathione levels; it also has a significant influence on ion Fe^{2+} chelation, nitric oxide and other reactive oxidative species scavenging. S-enantiomer of lipoic acid was more effective than the R-enantiomer when administered 1 hour before ischemia (Cardoso do Vale et al., 2003; Panigrahi et al., 1996). Lipoic acid administration attenuates liver ischemia-reperfusion injury (IRI) via the PI3-kinase/AKT pathway which play a pivotal protective role in IRI. Lipoic acid pretreated organs reduce postischemic activation of NF-kappa B and activating protein-1 (Panigrahi et al., 1996). To addition of its protective antioxidant effects, Haramaki et al., 1993, proposed that lipoic acid improve the cardiac recovery after ischemia, similarly, lipoic acid is reported for its effect on glucose uptake activity (Jacob et al., 1996).

α -lipoic acid is not without adverse effect if the dose and the route of administration are not carefully regulated. Patients exposed to very high dose of lipoic acid suffer adverse effects if thiamine deficiency is ignored. It is advisable to test the patient for thiamine deficiency before administration of lipoic acid (Gal, 1965).

Intraperitoneal administration of high doses of α -lipoic acid intraperitoneally to rats may cause fatal complications which can be averted with the prior administration of thiamine. Researchers are in general agreement that α -lipoic acid is capable of scavenging hydroxyl radicals, hypochlorous acid, and singlet oxygen, but not hydrogen peroxide, peroxy, and superoxide (Freisleben et al., 2000). It prevents DNA strand break up induced by singlet oxygen (Passwater et al., 1995). Lipoic acid is rightly so regarded as a dual antioxidant owing to its pro-oxidant effect at higher doses and very effective antioxidant action at low doses along with its characteristic ability to act as an antioxidant in fat- and water-soluble tissues in both its oxidized and reduced forms.

8.2. Coenzyme Q10

Coenzyme Q10 (CoQ) is also termed to be ubiquinone owing to its omnipresence in almost all cells. A lipid-soluble benzoquinone, COQ, is an essential component for electron transport in oxidative phosphorylation of mitochondria (mitochondrial respiratory chain) (Sunamori et al., 1991). Principally it acts as an electron carrier between the NADH and succinate dehydrogenases and the cytochrome system (Sunamori et al., 1991; Kagan et al., 1998). CoQ functions as an intracellular antioxidant, presumably by preventing both the initiation and propagation of lipid peroxidation (Ernster, 1993; Ernster, 1993).

When the heart experiences oxidative stress, the amount of CoQ decreases which triggers a signal for increased CoQ synthesis (Das and Maulik, 1995 and Crestanello et al., 1996). As it is synthesized by *de novo* synthesis CoQ can be endogenously regenerated and is capable of acting as an antioxidant to reduce oxidative damage during reperfusion (Beyer, 1992; Sugawara et al., 1990). CoQ has a potential antioxidant effect in the brain by reducing lactate concentration, inhibiting lipid peroxidation and improves recovery of brain metabolism in ischemic condition (Matthews et al., 1998; Liang et al., 2017).

Mitochondria are not the only site of action for antioxidant activity of CoQ, any cell exhibiting CoQ is expected to have beneficial effects of its protective actions (Sohal and Forster, 2007) making CoQ an ideal therapeutic agent to investigate in cerebral ischemia-reperfusion injury (Garrido-Maraver et al., 2014).

8.3. Trimetazidine

Trimetazidine, 1-(2,3,4-trimethoxybenzyl)piperazine hydrochloride is a FDA approved an anti-ischemic drug used in myocardial infarction and angina pectoris (Kutala et al., 2006). Trimetazidine (TMZ) exerts its actions without any alteration of hemodynamics of the heart (Lopaschuk et al., 2003). Principally it suppresses mitochondrial 3-ketoacyl-CoA thiolase (3-KAT) thereby reducing the free fatty acid metabolism and balancing the cardiac metabolism. TMZ positively modulates the energy homeostasis of the cells under ischemic stress or cells deficient of the energy substrates (Kantor et al., 2000; Guarnieri et al., 1993). TMZ is reported to preserve the cellular homeostasis by controlling intracellular acidosis and calcium overload in the cells thereby conserving the valuable ATP stores to meet the energy requirements (Mironova et al., 2001). The administration of TMZ is found to have beneficial effects on antioxidant enzymes in the brain by limiting the depletion of GSH (Abdel-Salam et al., 2011).

The pathogenesis of cerebral ischemia and myocardial ischemia leading to an array of critical cellular changes has similarities in a mechanism of cell death. These changes in cellular and mitochondrial levels are responsive to TMZ (Harpey et al., 1989; Kay et al., 1995). Being lipophilic, TMZ crosses the blood-brain barrier (BBB) ensures the availability at the target site providing prominent neuroprotective agent in cerebral ischemia/reperfusion (I/R) injury. The metabolic effects of TMZ during ischemia are attenuation of intracellular acidosis while in reperfusion it was accompanied by an acceleration of the resynthesis of phosphocreatine and a larger reconstitution of the ATP pool. Hence, TMZ has protected the ATP reserves by streamlining the ATP-producing processes, probably at the mitochondrial level (Dezsi, 2016; Dhote and Balaraman, 2008).

9. RECENT DEVELOPMENTS, FUTURE OPPORTUNITIES AND CHALLENGES

In the recent past, the renewed interest in stroke and reperfusion injury has driven numerous investigations of neuroprotective agents using various murine models of stroke. Many of these agents exhibited potent antioxidant activity indicated by marked changes in biomarkers of oxidative stress. The pharmacological activity extends from scavenging of superoxide anions to attenuating the oxidation of lipid peroxides. Many of these antioxidants do have a major effect on inflammation as well as cell damage due to apoptosis and necrosis. A summarized display of the various stages of pharmacological and clinical research has been given in the tabular form (Table 1 and Table 2).

Having said that extensive research is driving the development of new antioxidant agents which may have potent neuroprotective activity in preclinical stages, their translation in clinical therapeutics is still debatable (Gilgun-Sherki et al., 2002; Flores et al., 2014). Looking at the stringent criterion for clinical studies and slow pace of antioxidant-based neurotherapy development, use of the innovative approach to ensure realistic translation of preclinical gains in robust clinical strategies is the need for scientific research.

Table 1. Neuroprotective agents in phases of clinical development.

Neuroprotective Agents	Mechanism of Action	Stage of Clinical Development
Desmoteplase (Broussalis et al., 2012)	Activates plasminogen conversion to the serine protease, plasmin	Phase 2, 3 and 4 ongoing
Tenecteplase (Broussalis et al., 2012)	Selectively converts thrombus-bound plasminogen to plasmin	Phase 2
Anctrod (Broussalis et al., 2012)	Cleaves fibrinogen rather than fibrin	Phase 3
Edaravone (Broussalis et al., 2012)	Increases eNOS and decreases iNOS	Phase 4
Eptifibatide (Mestre et al., 2013)	Reversibly binds to the platelet receptor glycoprotein (GP) IIb/IIIa of human platelets	Phase 1 and phase 2
Ebselen (Azad and Tomar, 2014)	Reduction of ROS	Phase 3
Minocycline (Veltkamp and Gill, 2016)	Reduction of microglial activation reduced NO production, and inhibition of apoptotic cell death	Phase 2
Triiodothyronine (T3) nanoparticle (Mdzinarishvili, 2012)	Non-genomic T3 activation of nitric oxide signaling and vasodilation. Crosses the BBB via a specific transporter called monocarboxylate 8 (MCT8)	—

Table 2. List of various herbal antioxidants investigated using the various model of ischemia/reperfusion injury.

Antioxidant	Stroke Model	Dose and Route	Biomarkers Evaluated
<i>Canna indica</i> roots (Talluria et al., 2018)	BCCA; Male Wistar rats	400-800 mg/kg; PO	SOD, CAT, and MPO
Hexahydro-curcumin (Wicha et al., 2017)	MCAO; Male Wistar rats	20-40 mg/kg; IP	SOD, GSH, and GPx
Grape seed Procyanidin (Kong et al., 2017)	Transient MCAO; male SD rats	50 mg/kg; IP	GPx
Kukoamine A (Liu et al., 2016)	Permanent MCAO; Male SD rats,	5,10, 20 mg/kg; IV	SOD
Nobiletin (Zhanga et al., 2016)	Permanent MCAO; Male SD rats,	25 mg/kg; IP	HO1, SOD, and GSH
<i>Pentapetes phoenicea</i> (Sravanthi et al., 2016)	BCCA; Male Wistar rats	100 mg/kg; PO	SOD, CAT, and GPx
Arjunolic acid (Yaidikar et al., 2015)	MCAO; Wistar rat	10 and 20 mg/kg; PO	SOD, CAT, GSH, and GPx
Pinocembrin (Saad et al., 2015)	BCCA; Male Wistar rats	10 mg/kg; PO	LPO, GSH
Solasodine (Sharma et al., 2014)	BCCA; Male Wistar rats	100 and 200 mg/kg; PO	SOD, CAT, GSH, and LPO
Sesamin (Ahmada et al., 2014)	MCAO; Swiss Albino mice	30 mg/kg; IP	SOD, GSH, and LPO
Calycosin (Guo et al., 2012)	MCAO; Sprague Dawley rat	7.5,15,30 mg/kg; PO	SOD, CAT and GPx
S-Nitrosoglutathione (Khan et al., 2012)	MCAO; Wistar rats	3 micro mol/kg; IP	SIN-1, GSNO
Cymbopogon martini (Buch et al., 2012)	BCCA; Wistar rats	50-100 mg/kg; PO	SOD, CAT, GSH, and GPx
Ginsenoside (Ye et al., 2011)	MCAO; Swiss albino mice	50 mg/kg; IP	SOD, CAT, GSH, and GPx
Shikonin (Wang et al., 2010)	MCAO; male Kunming mice	50, 25, and 12.5mg/kg; PO	SOD, CAT, and GPx
<i>Bacopa monniera</i> (Saraf et al., 2010)	Transient ICA; Wistar rats	120 mg/kg; PO	LPO

BCCA, Bilateral carotid artery occlusion; MCAO, Middle cerebral artery occlusion; GSNO, S-Nitrosoglutathione; SIN-1, 3-Morpholinosydnone imine HO-1, Heme oxygenase-1; ICA, Intracarotid artery occlusion; PO, Per oral; IV, Intravenous; IP, Intraperitoneal

Very often reports of potent neuroprotection promised in preclinical studies by agents having an excellent reduction in infarct size fails to in translating realistic improvement in clinical trials. The reasons for this discrepancy are associated with disagreements in etiology, age, co-morbidities, therapeutic time window, optimum doses to its appropriate route of administration in preclinical and clinical milieu during the stroke (Gilgun-Sherki et al., 2002;

Flores et al., 2014). Classical example reinforcing these limitations is disodium 2,4-disulfophenyl-N-tert-butyltrione (NXY-059).

NXY-059 acts by trapping free radicals during reperfusion and ischemic episode which attributed to its anti-ischemic activity (Bath et al., 2009; Day et al., 2009). NXY-059 exhibited 43% attenuation of infarct volume indicating potent neuroprotection in a stroke model. Similarly, non-human primates (marmosets) model which closely resembles clinical etiology of stroke also confirmed neuroprotection induced by NXY-059. It fulfilled all STAIR criteria which revolves around post-stroke neurological recovery and hence promised a breakthrough in the treatment of stroke. The initial clinical study, Stroke-Acute Ischemic NXY Treatment (SAINT I), encouraged researches as it indicated a significant reduction in disability after 3 months of stroke when patients treated with NXY-059 in combination with thrombolysis (Lees et al., 2006). More elaborate and statistically powerful SAINT II study could not endorse the earlier potent outcomes and pooled data of two studies indicated a lack of functional improvements and benefits after NXY-059 (Diener et al., 2008). Other examples in the list are tirilazad (U74006F), a 21-aminosteroid which scavenges ROS, inhibits lipid peroxidation (Umemura et al., 1994) and edaravone (3-methyl-1-phenyl-2-pyrazoline-5-one) (Feng et al., 2011) (117 of SMI). However, edaravone is approved in Japan in spite of limited clinical data for acute ischemic stroke.

These examples emphasize the need for streamlined and aligning preclinical studies with robust clinical study criteria. The existing discrepancies are lack of pharmacokinetic considerations before treatment optimization, neglected co-morbidity status, inappropriate therapeutic time window, missed primary endpoints on efficacy and homogeneity of animals induced with stroke. These discrepancies seem to be just a broad overview of major limitations of current preclinical models to match clinical etiology of stroke and criteria of clinical studies. It has been suggested that preclinical studies can also be phased out on the lines of clinical trials where phase I would aim to discover or investigate pathophysiological mechanisms of a proposed treatment. While phase II pre-should evaluate the efficacy and safety of a drug and phase III must be conducted in the international, multicentre preclinical setup is required to confirm the efficacy of the proposed therapeutic agent. Similarly, the registration of preclinical studies for primary and secondary endpoint and its definitions in the registry, which are regularly followed in clinical trial registration protocol, must be made mandatory for all preclinical studies.

CONCLUSION

There are numerous more promising approaches which are aimed toward neuroprotection as well as cognitive recovery. Despite the pitfalls of current techniques, the translational activities are being refined with continuous enrichment of current scientific know-how of stroke etiology and glaring gaps in transition to clinics. Further innovative concepts and continuous exploration of the novel hypothesis will definitely result in the development of the new drug for the treatment of stroke in the near future.

OREGANO: PROPERTIES, USES AND HEALTH BENEFITS

EDITOR: Gema Nieto Martínez

SERIES: New Developments in Medical Research

BOOK DESCRIPTION: This book reviews and discusses oregano containing several potent antimicrobial, antioxidant compounds that may contribute to benefit the nervous and cardiovascular systems.

HARDCOVER ISBN: 978-1-53616-284-4

RETAIL PRICE: \$230

PALLIATIVE CARE: THE ROLE AND IMPORTANCE OF RESEARCH IN PROMOTING PALLIATIVE CARE PRACTICES: REPORTS FROM DEVELOPING COUNTRIES. VOLUME 3

EDITOR: Michael Silberman

SERIES: New Developments in Medical Research

BOOK DESCRIPTION: This book owes its origins in large measure to physicians and nurses in 30 countries globally, who decided to devote their time, energy, compassion and goodwill, to the promotion of palliative care in their countries and communities, yet they lack solid evidence-based data to rely upon while extending their treatment to both patients and family members.

HARDCOVER ISBN: 978-1-53616-211-0

RETAIL PRICE: \$230
